

# Clinical Hematology

# PLATE I

*The appearance of centrifuged blood in various conditions*

A. Normal blood

B. Anemia associated with chronic infection

C. Iron-deficiency anemia The blood plasma is very pale

D. Chronic myelocytic leukemia There are distinct layers of white corpuscles and of platelets above the red corpuscles

E. Post hepatic jaundice and moderate anemia In this case the coloring of the blood plasma is due to biliar obstruction rather than to increased blood destruction

F. Pernicious anemia Note the small amount of packed red corpuscles, the very narrow layer of leukocytes and platelets, and the coloring of the blood plasma due to hyperbilirubinemia

G. Polycythemia

(The blood was collected and treated as described on page 110)

# Preface

MORE than three decades have passed since I first began the task of assembling what was known about hematology in book form. Even then, the undertaking was not easy. Since that time, hematology has developed to a degree unmatched by any other field of medicine, in scope as well as in the depth of our understanding. Hematology now encompasses broad aspects of cytology, biochemistry, molecular biology, biophysics and immunology, not to speak of the various ramifications of clinical medicine.

The first six editions of *Clinical Hematology* were written entirely by me. With each edition the task has become more challenging and it has been more and more difficult to do justice to all dimensions of this remarkable field.

In planning the Seventh Edition, therefore, I enlisted the collaboration of some of my present and former associates. Their names are given on the title page. They were chosen because of their special interest in certain aspects of hematology, in addition to their thorough understanding of the whole field of hematology and their proved qualifications.

The organization of the book has been revised in keeping with present-day needs. In Part I, the approach to hematologic problems is considered from the viewpoint of the clinician. The principles of hematologic examinations are discussed and the simpler methods are outlined for the physician's own use. In addition, the principles and pitfalls of modern machines are presented. These discussions are presented so that the person who carries the ultimate responsibility for the patient will have enough understanding to do so with

confidence. This book, however, is not intended to be a laboratory manual.

In Part II a thorough account is given of the essentials of cytology, physiology, and biochemistry as they apply to the hematopoietic system. Such an understanding is essential for the intelligent and effective application of modern-day knowledge to medical practice. To attempt to practice hematology without an understanding of the normal hematopoietic system, as described in Part II, and without a physiologically basic concept regarding the approach to a hematologic problem would be like trying to sail in the open sea without landmarks or instruments and under a sky without stars.

To aid in the approach to the different varieties of hematologic problems, chapters and subsections which introduce the various areas or types of problems have been prepared; eg, the approach to the patient with anemia (Chapter 13), a kinetic approach to normocytic anemias (Chapter 19), an approach to hemolytic anemias (Chapter 20), a diagnostic approach to the bleeding disorders (Chapter 33), and the approach to the patient with disorders of the phagocytic and lymphatic systems (Chapter 40). In regard to treatment, the approaches are as diverse as hematologic conditions are varied.

In order to bring together in a single volume the ever-expanding body of information pertaining to clinical hematology, we have condensed some of the material found in earlier editions. Methodology, for example, has been given less space because advanced technology has produced sophisticated machines that have rendered it unnecessary for

the physician to carry out as many procedures as he used to perform. Yet he must understand these procedures—their purpose, their degree of reliability, and their pitfalls—and he must continue to be at home with elementary morphology, such as that required for examination of the blood smear and the bone marrow. Consequently, discussions of the latter topics have not been abbreviated. In hematology, morphologic examinations hold importance equal to the medical interview and the physical examination and should never be neglected. The morphologic descriptions are supported by 24 plates in color, most of which are new.

We have attempted to control the size of the book, but not at the expense of thoroughness and excellence. Furthermore, our original policy of providing, insofar as possible, careful and complete documentation, still obtains. As in past editions, reference lists are selective, as are citations in the text. When necessary, preference has been given to the latest report on a subject, in which the interested reader may find additional references to earlier literature. Whenever possible, comprehensive reviews and monographs have been listed. In citing the literature when a study has been carried out by more than two authors only the name of the first is given. Our apology is offered to those whose names are not listed.

In keeping with the decisions of the editorial boards of *Blood* and of the *British Journal of Haematology*, as well as other publications, we have adopted most of the units of the system recommended by the International Committee for Standardization in Hematology. These and their former equivalents appear inside the back cover of this book, as does our system of abbreviations. The style adopted for bibliographic material is that recommended by the *Index Medicus* of 1973.

Although each co-author, including the senior author, has assumed primary responsibility for certain chapters, no chapter is solely the work of one person, and all the material in this book has been thoroughly reviewed and edited by the senior author. Each member of the team has contributed in

some degree to chapters written by others, and all have utilized the material of earlier editions when this was appropriate.

As always, the preparation of a new edition of this book has been a rewarding though arduous task. Today's young hematologist probably has no conception of the rate at which his specialty has developed, especially since the mid-twenties. Clinical hematology exemplifies the ways in which clinical medicine has fed the basic sciences with questions and with clues, and the basic sciences in turn have illuminated human disease. The science of nutrition, for example, was enormously stimulated by the investigations that established the role of vitamin B<sub>12</sub> in pernicious anemia and those demonstrating the role of other vitamins in hematopoiesis. Exploration into the phenomenon of sickling opened the whole field of molecular biology and brought to light the many hemoglobinopathies of which we are now aware. These remarkable advances in turn prompted investigation of the pathogenesis of thalassemia, which revealed pathogenetic mechanisms hitherto unknown. Basic investigations of carbohydrate metabolism and of the metabolism of the red cell resulted in the recognition of enzyme deficiencies of the red cell, some of which have serious consequences. Many other examples of the interplay of basic science and clinical medicine could be cited.

We should like to express our gratitude to Dr. Arthur Haut of the University of Arkansas for two chapters; Dr. Wallace N. Jensen of George Washington University for one chapter; Dr. A. S. Wiener for reviewing the chapter on blood groups and blood transfusion and making valuable suggestions; Dr. Phaedon Fessas for valuable comments regarding the chapter on thalassemia; Dr. George Stamatoyannopoulos for his advice regarding hereditary polycythemia; Dr. W. A. Schroeder for his comments on hemoglobinopathies; and, for their comments and criticisms of various other chapters, Doctors E. J. Hershgold, Gerald Rothstein, R. E. Lynch, James Kushner, Dana Wilson and Joseph Sannella of the University of Utah, Phillip M. Allen, Byrd S. Leavell, Charles

Hess and Oliver B. Bobbit of the University of Virginia, Alan Winkelstein and Sallie Boggs of the University of Pittsburgh, and Frixos Paraskevas of the University of Manitoba.

We are especially indebted to Dr. Albert Clarysse, formerly Assistant Professor of Medicine, University of Utah, for his skillful preparation of photomicrographs, as well as to Miss Anne Sasyniuk of the University of Manitoba; to those who generously furnished illustrations from their publications or personal collection; and to their publishers. These include Dr. Dorothea Zucker-Franklin, Dr. Walter Seggers, Dr. C. L. Conley, and Dr. William McDivitt.

Secretarial assistance has been provided by Vreni Bithell, Carolyn Bailes, Franklin White,

Georganna Barnes, Mary Welch, and Pearl Emery, but it is with very special appreciation that the many long hours of hard work and the extraordinary efficiency of the senior author's secretary, Mrs. Katharyn Rees, are acknowledged. Without such unstinting effort his task would have been much more difficult.

It is a special pleasure, also, to acknowledge the skill and whole-hearted cooperation of the publishers, Lea & Febiger and their staff, especially Mr. T. J. Colaiczzi and Miss Emily Anderson.

As in the past, I must express my sincere appreciation of the understanding and unselfish support of my wife. With this edition, the support of the wives of my collaborators also is gratefully acknowledged.

MAXWELL M. WINTROBE

*Salt Lake City, Utah*

# Contents

## Part I. Introduction

1. The Approach to Hematologic Problems 3
  - General considerations* 3
  - Principles of hematologic examination* 6

## Part II. The Normal Hematopoietic System

### Section 1. *Basic Cytology* 41

#### 2. Origin and Development of the Blood and Blood-Forming Tissues 41

- Proliferation and differentiation of cells* 42
- Hematopoietic stem cells* 49
- Blood formation in the embryo and fetus* 53
- Blood of newborn infants and children* 56
- Extramedullary hematopoiesis* 57
- Medullary hematopoiesis* 59
  - Methods of obtaining bone marrow specimens* 63
  - Preparations of bone marrow specimens* 66
  - Examination of bone marrow specimens* 67
  - Indications for marrow aspiration* 73
  - Indications for bone marrow biopsy* 75

### Section 2. *The Erythrocyte* 80

#### 3. Morphology, Intrinsic Metabolism, Function, Laboratory Evaluation 80

- Discovery of the erythrocyte and early studies* 80
- Normal development of the erythrocyte* 81
- The mature erythrocyte* 91
- Laboratory evaluation of erythrocytes* 109

4. Production of Erythrocytes	135
<i>Nutritional requirements for red cell production</i>	135
<i>Iron metabolism</i>	154
<i>Hemoglobin structure and synthesis</i>	167
<i>Control of erythropoiesis</i>	179
5. Destruction of Erythrocytes	195
<i>The life span of the erythrocyte</i>	195
<i>Erythrocyte aging</i>	200
<i>Mechanisms of red cell destruction</i>	201
<i>Sites of erythrocyte destruction</i>	204
<i>Hemoglobin catabolism</i>	208
Section 3. <i>Leukocytes, Spleen, and the Reticuloendothelial System</i>	221
6. Granulocytes and Monocytes	221
<i>Morphology and chemical properties</i>	221
<i>Leukocyte kinetics</i>	243
<i>Neutrophil series—Kinetics, properties, and function</i>	244
<i>Eosinophil series—Kinetics, properties, and function</i>	262
<i>Basophil series—Kinetics, properties, and function</i>	265
<i>Monocyte series—The mononuclear phagocyte system—Kinetics, properties, and function</i>	267
7. Lymphocytes and Lymphatic Tissues and Their Relation to Humoral and Cellular Immunity	286
<i>The lymphatic system</i>	287
<i>Development of the immune system</i>	293
<i>Lymphokinetics</i>	298
<i>Lymphocyte function</i>	305
<i>Complement</i>	333
<i>Methods of examination</i>	337
8. The Reticuloendothelial (Mononuclear Phagocyte) System and the Spleen	351
<i>The reticuloendothelial (mononuclear phagocyte) system (RES, MPS)</i>	351
<i>The spleen</i>	354
<i>Structure</i>	354,
<i>Changes in the blood following splenectomy</i>	358
<i>Functions</i>	360

## Section 4. *Platelets, Hemostasis, and Coagulation* 371

9. Platelets and Megakaryocytes: The Physiology of Primary Hemostasis	372
---	-----

<i>The blood platelet</i>	372
<i>The megakaryocyte</i>	380
<i>Kinetics of thrombopoiesis</i>	383
<i>The vascular phase of hemostasis</i>	389
<i>The platelet phase of hemostasis</i>	390
<i>Homeostatic control mechanisms</i>	399
<i>Miscellaneous platelet functions</i>	399

## 10. Blood Coagulation 409

<i>The coagulation factors</i>	409
<i>The physiology of coagulation</i>	421
<i>Homeostatic control mechanisms</i>	430
<i>The fibrinolytic enzyme system</i>	432
<i>Homeostatic significance of coagulation</i>	438

## Section 5. Blood Groups and Blood Transfusion 451

### 11. Transfusion of Red Cells 451

<i>Blood groups</i>	451
<i>Methods of blood typing</i>	469
<i>Collection and preservation of blood</i>	472
<i>Blood transfusion</i>	474
<i>Clinical use of plasma and plasma derivatives</i>	488

### 12. Leukocyte and Platelet Antigens and Transfusions 498

<i>Leukocyte antigens</i>	498
<i>Leukocyte transfusions</i>	508
<i>Platelet antigens</i>	511
<i>Platelet transfusion</i>	515

## Part III. Disorders of the Red Cells

### Section 1. Introduction 529

#### 13. The Approach to the Patient with Anemia 529

<i>The approach to the diagnosis</i>	530
<i>Manifestations of anemia</i>	532
<i>Evaluation and diagnosis</i>	538
<i>Classification of anemia</i>	546
<i>Treatment of anemia</i>	550
<i>Anemia in pregnancy</i>	555
<i>Features of anemia unique to infants and children</i>	558
<i>Nutritional considerations in anemia in infants and children</i>	561

' Section 2. <i>Macrocytic Anemias</i>	566
14. <i>Macrocytosis and Macrocytic Anemias</i>	566
<i>Significance of macrocytosis</i>	566
<i>Non-megaloblastic, macrocytic anemia</i>	567
<i>Megaloblastic anemia</i>	568
15. <i>Pernicious Anemia</i>	602
<i>History</i>	602
<i>Incidence</i>	603
<i>Etiology and pathogenesis</i>	604
<i>Clinical manifestations</i>	610
<i>Laboratory findings</i>	614
<i>Course, prognosis, and complications</i>	615
<i>Pathology</i>	616
Section 3. <i>Anemias Characterized by Impaired Iron Metabolism</i>	621
16. <i>Anemias Characterized by Deficient Hemoglobin Synthesis and Impaired Iron Metabolism</i>	621
<i>Definition and detection</i>	621
<i>Etiology and pathogenesis</i>	622
<i>Laboratory tests useful in detection and differential diagnosis</i>	626
<i>Diagnostic approach</i>	633
17. <i>Iron Deficiency and Iron-Deficiency Anemia</i>	635
<i>History</i>	635
<i>Iron-deficiency states</i>	636
<i>Prevalence</i>	638
<i>Etiology</i>	638
<i>Clinical manifestations of iron deficiency</i>	649
<i>Laboratory findings</i>	656
<i>Management</i>	660
18. <i>The Anemia of Chronic Disorders and the Sideroblastic Anemias</i>	671
<i>Anemia of chronic disorders</i>	671
<i>Sideroblastic anemias</i>	678
Section 4. <i>Normocytic Anemias Other than Hemolytic Anemias</i>	693
19. <i>The Normocytic, Normochromic Anemias</i>	693
<i>Classification and diagnostic approach</i>	693
<i>Acute posthemorrhagic anemia</i>	695

<i>Congenital dyserythropoietic anemias</i>	699
<i>The anemia of chronic renal insufficiency</i>	700
<i>Anemia in cirrhosis and other liver diseases</i>	706
<i>Anemias associated with endocrine disorders</i>	709

Section 5. <i>Hemolytic Anemias</i>	717
20. The Hemolytic Disorders: General Considerations	717
<i>Definitions</i>	717
<i>Pathogenesis and classification</i>	719
<i>Clinical manifestations</i>	722
<i>Laboratory manifestations</i>	725
<i>Diagnostic approach</i>	737
<i>Therapy</i>	739
<i>Acquired hemolytic anemia resulting from infections, from chemical agents, and from physical agents</i>	740
<i>Acquired hemolytic anemia associated with hypophosphatemia</i>	746
21. Hereditary Spherocytosis and Other Hemolytic Anemias Associated with Abnormalities of the Red Cell Membrane	751
<i>Hereditary spherocytosis</i>	751
<i>Hereditary elliptocytosis</i>	759

## Part IV. Disorders of Platelets and Hemostasis

### Section 1. *Approach to Problems of Hemostasis and Coagulation* 1043

#### 33. The Diagnostic Approach to the Bleeding Disorders 1043

<i>Clinical evaluation of the bleeding patient</i>	1043
<i>Laboratory methods for the study of hemostasis and blood coagulation</i>	1049
<i>Tests of the vascular and platelet phases</i>	1049
<i>Tests of the coagulation phase</i>	1056
<i>Initial laboratory approach</i>	1062
<i>Laboratory evaluation in the newborn</i>	1067

### Section 2. *Disorders of Platelets* 1071

#### 34. Quantitative Variations of Platelets in Disease; Thrombocytopenia and Thrombocytosis 1071

<i>Thrombocytopenia</i>	1071
<i>Immunologic platelet destruction</i>	1075
<i>Idiopathic thrombocytopenic purpura</i>	1075
<i>Other forms of immunologic platelet destruction</i>	1090
<i>Deficient platelet production</i>	1095
<i>Thrombocytopenia due to abnormal platelet pooling</i>	1098

<i>Miscellaneous forms of thrombocytopenia</i>	1099
<i>Thrombocytosis</i>	1103
<i>Thrombocythemia</i>	1103
<i>Reactive thrombocytosis</i>	1107

### 35. Qualitative Disorders of Platelet Function 1119

<i>Hereditary disorders of platelet function</i>	1119
<i>Acquired disorders of platelet function</i>	1128

### 36. Bleeding Disorders Caused by Vascular Abnormalities 1136

<i>Autoimmune vascular purpuras</i>	1136
<i>Purpura associated with infections</i>	1143
<i>Structural malformations of vessels and perivascular tissues</i>	1144
<i>Miscellaneous vascular purpuras</i>	1151

## Section 3. Coagulation Disorders 1158

### 37. The Hereditary Coagulation Disorders 1158

<i>Nomenclature</i>	1158
<i>Principles of pathophysiology</i>	1159
<i>Hemophilia A (Factor VIII deficiency)</i>	1161
<i>Hemophilia B (Factor IX deficiency)</i>	1172
<i>Factor XI deficiency</i>	1173
<i>Disorders of fibrinogen</i>	1174
<i>Factor XIII deficiency</i>	1176
<i>Deficiency of prothrombin</i>	1177
<i>Factor V deficiency</i>	1177
<i>Factor VII deficiency</i>	1178
<i>Factor X deficiency</i>	1178
<i>Factor XII deficiency</i>	1179
<i>Von Willebrand's disease</i>	1179
<i>Miscellaneous hereditary coagulation disorders</i>	1183
<i>Treatment</i>	1183
<i>Replacement therapy</i>	1184

### 38. Acquired Coagulation Disorders 1201

<i>Deficiencies of vitamin K-dependent factors</i>	1201
<i>Hemorrhagic disease of the newborn</i>	1201
<i>Hepatic disease</i>	1205
<i>Pathologic inhibitors of coagulation</i>	1208
<i>Diffuse intravascular coagulation</i>	1211
<i>Fibrinogenolysis</i>	1224
<i>Miscellaneous disorders</i>	1226

39. Thrombosis and Antithrombotic Therapy	1233
<i>Pathophysiology of thrombosis</i>	1233
<i>Hematologic methods for the detection of thromboembolic disease</i>	1238
<i>Anticoagulant therapy</i>	1238
<i>Miscellaneous antithrombotic agents</i>	1246

## Part V. Disorders Characterized by Adenopathy, Splenomegaly, and/or Abnormalities of Leukocytes or Immunoglobulins

Section 1. <i>Approach to Disorders of the Phagocytic and/or Lymphatic Systems</i>	1255
40. Diagnostic Steps in the Evaluation of the Patient with Abnormalities of Leukocytes or Immunoglobulins, or Lymphadenopathy, Splenomegaly, Fever of Unknown Origin, or Recurrent Infection	1255
<i>Examination of the blood</i>	1256
<i>Bone marrow examination</i>	1258
<i>Lymph node examination</i>	1259
<i>Examination of the spleen</i>	1262
<i>Fever of unknown origin</i>	1263
<i>Recurrent infections</i>	1263
Section 2. <i>Non-neoplastic Disorders of Leukocytes and RES</i>	1266
41. Variations of Leukocytes in Disease	1266
<i>Leukocytes in inflammation</i>	1266
<i>The neutrophil series</i>	1268
<i>The eosinophil series</i>	1282
<i>The basophil series</i>	1286
<i>The monocyte-macrophage series</i>	1286
<i>The lymphocyte series</i>	1288
<i>Plasma cells</i>	1290
<i>Agranulocytosis and drug-induced neutropenia</i>	1290
<i>Leukemoid blood pictures</i>	1301
42. Quantitative, Morphologic, and Functional Disorders of the Granulocyte and Monocyte-Macrophage Systems	1313
<i>Quantitative disorders of granulocytes</i>	1313
<i>Disorders of phagocytic leukocytes characterized by morphologic changes</i>	1319
<i>Functional disorders of leukocytes not characterized by morphologic changes</i>	1326

*Disorders involving the monocyte-macrophage system—the "storage diseases" Histiocytosis X* 1330

  - Electron Microscopy

### **General Considerations**

Certain diseases primarily affect the blood and blood-forming tissues and, even more frequently, disorders of other organ systems result in alterations in the blood. Consequently, broadly defined, hematologic problems are common and diverse. Clearly, therefore, the approach to a hematologic problem must begin with a thorough history and a complete physical examination. Without these, laboratory investigation in any amount cannot be very useful and can even be confusing.

In addition to the history and physical examination, it is necessary to measure the volume of packed red cells (VPRC, hemato-

crit), the concentration of leukocytes (WBC), and the differential leukocyte count, and to examine the stained blood smear under the microscope. The erythrocyte sedimentation rate may be added as a useful, nonspecific indicator of acute or chronic conditions. If a disorder affecting the blood is suspected, or if any abnormality is found in the aforementioned examinations and tests, additional studies may be indicated.

The point of departure in the hematologic evaluation generally is an objective observation of abnormality made during the physical examination (eg, pallor, lymphadenopathy, purpura, splenomegaly), or when the blood is examined (Fig. 1-1). The symptoms of hematologic disorders may be so varied and nonspecific that in themselves they may not suggest a hematologic problem. For example, unexplained fever, or extreme fatigability, may or may not be due to a hematologic disorder. However, a history of excessive bleeding under conditions which would not usually be expected to produce this symptom suggests a hematologic disorder.

The additional hematologic examinations which would be indicated if a hematologic disorder is suspected include measurement of the hemoglobin concentration, platelet count, reticulocyte and red blood cell counts, and calculation of the red blood cell indices. Thereafter, at each stage of the diagnostic process, other tests are selectively chosen according to the provisional diagnosis which

the physician may consider likely. In addition to the above-mentioned examinations, the tools available to the physician studying a hematologic problem include: (1) quantitative study of the bone marrow morphology; (2) microscopic anatomy by biopsy of the bone marrow, lymph nodes, liver, or other tissues; (3) radiographic anatomy of the chest, abdomen, or bones or other tissues as suggested by the examinations made up to that point; (4) bioassay and chemical assay of body tissues or fluids, including but not limited to plasma and urine; and (5) evaluation of physiologic function by following the fate of tracer substances. For tracing, normal metabolites such as iron may be labeled, or a nonphysiologic but noninjurious label may be attached to a normal substance or body constituent. A chromium-ion label for red cells or an iodine tag on transferrin are examples of the latter. Tracer methods require that the presence of the substance used as a label does not alter the normal physiology either qualitatively or quantitatively. Most often radioisotopes are used as the labels because of the relative ease of their subsequent identification and quantification. Sometimes the hazards accompanying these substances preclude their use in patients or in subjects of physiologic studies. The heavy isotopes which require mass spectrometry for their identification may sometimes be used in their place. Tracer studies have allowed great insight into normal and disordered physiology and in a number of situations are powerful tools for diagnosis.

Incisive points in the examination of the patient which especially relate to hematologic conditions and discussions of the various tools for diagnosis named above are presented in the chapters which focus on the problems identified by the various clues. Thus, examination of the bone marrow is discussed in Chapter 2. Techniques dealing with red cells in particular are discussed in Chapters 3 and 5. Techniques dealing with the study of granulocytes and monocytes are considered in Chapter 6, and those concerned with platelets and hemostasis and coagulation in Chapters 9 and 10. The approach to the study of

anemias in general is considered in Chapter 13, to specific types of anemia in Chapters 14, 16, 19 and 20, to problems of hemostasis and coagulation in Chapter 33, and to the patient with disorders of the phagocytic and lymphatic systems in Chapter 40. In the present chapter, only general principles concerned with the interpretation of hematologic data and certain details of hematologic technique are discussed because of their broad applicability to so much of that which follows.

It is important to stress that indiscriminate selection of a battery of hematologically oriented tests is not wise. Sometimes, however, when dealing with automated laboratories, it may be faster, no less accurate (depending upon the instrumentation), yet less costly in time and money to initially obtain a battery of hematologic data (to be discussed later) even for patients not suspected of having hematologic problems, in place of adherence to the selected items listed above. When utilizing some types of automated apparatus one may be led to forego the centrifugal determination of VPRC in patients without evident hematologic problems. However, when blood disease is suspected the VPRC should not be omitted.

Successful and intelligent management of disease requires a diagnosis or at least the best approach to a diagnosis. To achieve the diagnosis the physician engages in a deductive reasoning process. From the glimpses into the disordered physiology or anatomy of the diseased patient which are allowed by the assembled evidence, he must conceptualize the entire disease process. His hypothesis regarding the latter must include identification of those key points in the evolution of the disease which, if altered by therapy, would arrest or reverse the illness. Then, he must test his hypothesis by decisive action. The physician's role in this decision-making process requires that he be able to first answer the question, "What is the nature of the evidence which needs to be gathered?" and later, "Has all the relevant information been accumulated?" Uncertainty regarding these answers results in a diffuse testing and data-

# APPROACH TO HEMATOLOGIC DISORDERS

## Various Clues that Might Be Found

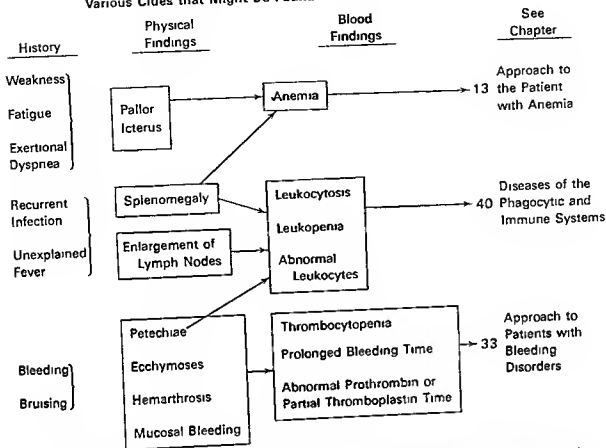

Fig. 1-1. This diagram relates sections of this book to clues from certain features in the *history*, *physical examination*, or *preliminary blood examination* which can guide the examiner toward the solution of a clinical problem

gathering exercise, which is disproportionately expensive and of limited if any value to the patient.

It is axiomatic that an understanding of the normal physiology of the blood, the bone marrow, the spleen, and the lymphatic tissues, and of the mechanisms of hemostasis is required for an orderly inquiry regarding the pathogenesis of derangements in these systems, and hence the pursuit of the diagnosis. Even an incomplete understanding of the disordered physiology provides some basis for management of those clinical problems which cannot be solved today. It also gives direction to investigative efforts which ultimately will provide the greatest relief for individuals suffering from as yet incurable problems in clinical hematology.

The diagnosis allows the physician to ap-

preciate the prognosis if one did not intervene with therapy. Knowledge of the prognosis, both with and without various modes of therapy, guides the physician in answering the three major questions of therapy:

*If he should treat,  
when he should treat,  
and with which modality?*

All too often, one encounters insufficient patience in attempting to achieve a diagnosis and undue haste in attempting therapy. The therapeutic measures, in particular the chemotherapeutic agents, available to hematologists in the present day carry a very substantial potential for doing harm. Potential gains must be weighed against potential risks.

The physician undertaking the management of a patient with a hematologic disorder

must possess more than a thorough understanding of normal physiology and of the normal course of the diseases with which he is dealing. He must also be mindful of the patient's fears and hopes and of those of his family. He must take the time to give the patient and his family some understanding of the illness, if there is one, and yet he must do this with sensitivity and sympathy. He must choose carefully each word he uses and must consider how his comments may be interpreted, or misinterpreted. The nature and course of certain hematologic disorders are such that in some patients reassurance may be far more important than any other measure the physician can offer. To undertake meaningless therapy, to treat only because of the magnitude of the white blood cell count, for example, without considering the psychologic effects of such attention to what may be a relatively minor manifestation of the disease, and to risk the possibility of injury by the therapeutic agents used, without considering the normal course of the disease in question, even when not treated, are errors of judgment which are all too common.

## Principles of Hematologic Examination

The correct interpretation of values obtained from examination of the blood depends equally upon a thorough knowledge of the normal values and of the *limitations or possible sources of error of the methodology* employed in generating the values for the specific patient. Often, the advantage afforded the hematologist in solving clinical problems lies as much in the care and precision practiced by the laboratory that he relies upon as in his own specialized knowledge. Small differences from the normal can allow important and valid inferences when laboratory technique is good; interpretation of even substantial differences from the normal may be hazardous when the methods relied upon are less reproducible, or less accurate, than those which we recommend. Carefully made observations and measurements in the laboratory, as in the physical examination, are the very

**Table 1-1. Sources of Error in Blood Cell Counts Introduced by Improper Handling of the Specimen\***

\*Applies to counts done by manual hemocytometer, and automated and electronic counter techniques

core of the most thoughtful analysis of a clinical problem. They begin as the blood sample is obtained. (Table 1-1).

### Obtaining the Specimen

Accurate and unequivocal labeling of the patient-source of the blood sample, and of the date it was secured, is essential. Small quantities of blood may be obtained by *puncture* of the lateral aspect of the distal phalanx of one of the patient's fingers, or, in infants, of the plantar surface of the heel. A sterilized (preferably disposable) styler or needle is used. Freely flowing blood obtained from these sites may be used for preparation of blood films, the platelet count, or for the microhematocrit method when venipuncture is not possible or is not preferred. Unless blood obtained for counting procedures is promptly mixed with suitable dry anticoagulants or diluents, agglomeration of platelets and other cells will occur, or fibrin strands or even a complete clot will form, and prevent reliable studies.

When several quantitative blood examinations are to be carried out, it is better to collect a few ml of blood from a vein. Suitably *anticoagulated*, this will allow dilutions and counts to be performed in a laboratory remote from the patient and at a later, more

convenient time. Although it is best to perform the counts within six hours after the blood has been drawn, counts will be satisfactory if the blood has been collected in EDTA and kept refrigerated for as long as 24 hours.<sup>27</sup> Several ml of venous blood are required if certain of the automated methods, to be described below, are to be employed for blood counting.

The venipuncture may be performed in one of the antecubital veins, with a sterile  $\#20$ ,  $1\frac{1}{2}$ " needle. One of the smaller veins of the forearm, or dorsum of the hand, may also be used, although if any of these sites is chosen a narrower needle ( $\#21$  or  $\#22$ , thin wall) is usually needed. In hospitalized patients, particularly in the obese, it is sometimes necessary to obtain blood from the femoral vein. The syringe and needle used to collect blood must be clean and dry; otherwise hemolysis will occur. Inexpensive needles, for single use, are commercially available. These are preferred by physicians and patients alike, because they are sterile and single use avoids the risk of transmission of homologous serum jaundice; they are sharp and free of burrs, thereby minimizing discomfort to the patient; and, ultimately, they are less costly than multiple-use needles which require hand processing for cleaning, sharpening, inspection, packaging, and sterilization following each use. Vacutainers are test tubes sealed under vacuum by a pliable stopper which may be punctured by the back end of a special needle held in its own adapter, after the forward end of the needle has been used to enter the vein in the usual fashion. With this device, the collection vessel also serves in place of the syringe.

After the blood is obtained, the tourniquet should be released before the needle is withdrawn. Direct pressure should be applied to the site of venipuncture to prevent hematoma formation. Several minutes of direct pressure will usually suffice, except in patients known or suspected of having thrombocytopenia or other derangements of the hemostatic system. In those individuals, at least five minutes may be required. The practice of flexing the patient's elbow with a small piece of gauze or

cotton in the antecubital fossa is often insufficient since pressure may be applied away from the point of puncture. It is better to elevate the patient's limb slightly and, with a piece of dry, sterile gauze or cotton over the puncture site, to apply pressure at the site with the thumb. It may be necessary to puncture these veins on many subsequent occasions, particularly in patients with significant illnesses. A few moments spent in the care of the vein after venipuncture will be returned manyfold through avoidance of frustration and discomfort on later occasions. Furthermore, if ecchymoses, hematomas, or other signs of technical problems develop at the venipuncture site, they may be readily interpreted by the patient as a true measure of the overall proficiency of the physician and his staff.

### Anticoagulants

An anticoagulant is required if venous blood is to be used for blood counting. The choice of anticoagulant and the ratio of blood to anticoagulant are of paramount importance. Dry anticoagulants are used to avoid dilution which would lower the concentration of the formed elements in the collected blood. The anticoagulant selected must not alter the size of the red cells, nor bring about their hemolysis; it must minimize aggregation of the platelets; it must minimize disruption of the leukocytes; and it must be readily soluble in blood. These qualities are best met by the dipotassium or tripotassium salt of ethylenediaminetetraacetic acid ( $K_2$ EDTA). The disodium salt ( $Na_2$ EDTA) is less quickly soluble but somewhat less expensive. Both of these salts are effective in the concentration of 1 mg/ml of blood. Greater concentrations may induce artifactual errors in the VPRC and other values.<sup>63,93,108</sup> Since a measured amount of dry anticoagulant is generally already present in the vessel used to receive the blood to be obtained by venipuncture, the operator must be certain that the volume of blood required ( $\pm 20\%$ ) for the amount of anticoagulant is actually

delivered into the vessel and promptly mixed with the anticoagulant. If too much blood is added, small clots may form; sometimes these are not easily noted but are, nevertheless, capable of altering the values. If too little blood is added, the red cells may be crenated, thereby falsely reducing the volume of packed red cells<sup>108</sup> and the corpuscular indices derived therefrom. Small bottles or other well-stoppered receptacles containing 3 or 5 mg of EDTA sufficient for 3 or 5 ml of blood, respectively, are popular. Small Vacutainers containing sufficient EDTA for 4 ml of blood have the advantage in that, when filled with a syringe pointing downward when its needle pierces the stopper, they have sufficient vacuum to assure their filling with the correct volume of blood, provided some excess blood remains in the syringe after the blood ceases to flow into them.

A mixture of dry ammonium oxalate and potassium oxalate, in the ratio of 3:2, is a satisfactory anticoagulant<sup>41</sup> which also avoids alteration in the volume of packed red cells.<sup>83</sup> Two mg of the mixture will serve to anticoagulate 1 ml of blood.<sup>41</sup> Either one of these oxalates used alone is inadequate, as the former causes red corpuscles to swell and the latter leads to shrinkage. The mixture, often called "balanced" or "double" oxalate, is more likely than EDTA to result in aggregation of platelets and, therefore, is less popular now as a general-purpose anticoagulant for hematology laboratories than formerly. However, double oxalate and not EDTA must be used as the anticoagulant for the "sucrose-hemolysis" test for paroxysmal nocturnal hemoglobinuria.<sup>84</sup>

Dry heparin may be used, but it is more costly than the double oxalate or EDTA and, since it may not mix readily or rapidly with blood, tiny clots may form. However, by comparison with blood from a hemophilic to which no anticoagulant need be added, it has been found that heparin does not alter the size of the corpuscular constituents of the blood. For this reason, heparinized blood has been used as a standard for comparison of the effects of various inorganic anticoagulants.

Since the formed elements of the blood tend to settle upon standing, and do so particularly in the presence of anemia, hyperfibrinogenemia, or hyperglobulinemia, it is essential that, prior to sampling for blood counting and other examinations, the venous blood be gently but thoroughly mixed. The specimen must also be inspected for macroscopically visible autoagglutination of red corpuscles and aggregation of platelets, and for the presence of clots. Insufficient attention paid to these simple matters may vitiate the significance of blood counts performed by the most costly robot apparatus, or by trained technologists.

#### Quantitative Analysis of the Formed Elements

Normally, and even in disease associated with severe anemia, the fraction of blood occupied by the red corpuscles is great enough to allow accurate quantitation of these cells simply by measuring their proportionate volume after centrifugation. The hematocrit described by Wintrobe<sup>175</sup> (Chapter 3) has the advantages of simplicity and high accuracy, and requires minimal technical skill. The Wintrobe tube may also be used to determine the erythrocyte sedimentation rate (page 125) prior to centrifugation of the sample, and afterwards to estimate the icterus index (page 214). The latter is a simple screening procedure to detect the possibility of hyperbilirubinemia. Normally the relative numbers of and volume occupied by leukocytes and platelets in the blood are too low to quantitate by measurement of the proportionate volume, which is about 0.5% to 1.0% of the total. Nevertheless, one can readily detect the presence of marked leukocytosis or thrombocytosis, or even leukopenia, by inspection of the reddish-gray (buffy) layer overlying the packed red cells in the Wintrobe hematocrit tube. This and other hematocrit techniques are discussed in Chapter 3.

The term "hematocrit" (G. *haima*, blood, + *kritē*, I separate) was at first used

to identify the *instrument* used to measure the proportionate volume of packed red cells (VPRC, PCV); ie, the particular type of centrifuge or the tube employed. Now, *hematocrit* is predominately used synonymously with the VPRC as determined by a centrifugal method. Unfortunately, the term "hematocrit" has also been applied to a value computed from measurements by automated devices of either the sizes of individual red cells<sup>40,66</sup> or the electrical conductivity of the blood.<sup>53,78,100</sup> Some investigators consider those values to be comparable to the VPRC.<sup>26,72,76,110</sup> Others,<sup>78,112</sup> including ourselves, do not. The computed values entail different principles than does the established Wintrobe method and they have unique sources of error as described later in this chapter. We will conform with current usage and employ the word hematocrit throughout this book to refer to all of these widely practiced methods of measurement. The term VPRC will be reserved for that value as determined by an acceptable centrifugal method (Chapter 3). VPRC will be used when specific differentiation from other methods is required.

## Enumeration

### Quantitation of Leukocytes and Platelets

This must be accomplished by enumerative procedures which measure the concentration of the leukocytes and platelets per unit volume, because of the small proportionate volume of these cells in the blood, and the irregularity of the relationship between their volume and numbers. Enumeration is also used to determine the concentration of red corpuscles ("red cell count") when that information is needed for the calculation of the corpuscular indices (Chapter 3). In both the traditional and the more recent automated procedures, two steps are required: (1) accurate dilution of the suspension to be studied, and (2) enumeration of the formed elements of interest, per unit volume of the diluted fluid.

## Traditional Procedures

The traditional procedure for blood counts has employed the Thoma<sup>145</sup> diluting pipet, or a variant of it. This consists of a capillary tube, graduated in relative units, containing a bulb in its upper portion. After blood is drawn to the mark in the capillary stem, diluent is drawn into the tube until the tube is filled to a mark in the short capillary stem above the bulb. The choice of dilution depends upon the concentration of particles to be enumerated. Ordinarily, a pipet allowing a dilution of 1:200 and 1:100 (v/v) is used for red cells, and another pipet which allows a dilution of 1:20 and 1:10 is used for leukocytes. A dilution of 1:100 is used for counting platelets except when thrombocytopenia is present, when a lesser dilution, such as 1:20, is employed. The correct diluent must be chosen according to the cells to be enumerated. For red cells, the diluent is an isotonic fluid such as Hayem's or Gowers' solution<sup>43</sup>; for leukocytes, Turk's diluting fluid is employed to hemolyze the usually more numerous red cells and stain the leukocytes; for platelets, the preferred diluent is 1% ammonium oxalate<sup>19</sup> with 0.1% to 0.44% EDTA, as this makes the red cells translucent under the phase contrast microscope, and the platelets assume a rounded shape<sup>130</sup> and are more readily recognized.

Unopettes are small, plastic reservoirs with flexible walls, containing a pre-measured ( $\pm 1\%$ ) volume of diluent suitable for a specified cell-counting procedure.<sup>171</sup> When filled with blood from a companion thin-walled glass capillary of uniform bore and specified length, the appropriate dilution of the blood specimen is achieved. Unopettes allow dilution with  $\pm 1\%$  to 2% accuracy if the recommended technique is followed, and individually are less costly than are the standard, blood-diluting pipets made of glass. However, as manufactured, Unopettes are not reusable; whether their disposable character results in a net saving in the cost of labor plus materials depends upon the individual laboratory. A modification to allow re-use has been described.<sup>32</sup>

Fig. 1-2 \*Improved Neubauer ruling (1924) with double line surrounding each group of sixteen small squares used in all-glass chambers to produce the optical phenomenon of a single translucent boundary line

After thorough mixing in the pipet, the diluted blood is delivered into a *hemocytometer* (counting chamber). The latter consists of a heavy glass slide with two accurately ruled platforms, each surrounded by a moat and covered by an optically flat coverslip held exactly 0.1 mm above the platforms. The chamber now used is the product of many modifications.<sup>14b</sup> That of Neubauer<sup>14c</sup> is still employed (Fig. 1-2). After the cells have settled to the floor of the platform, those lying within specified ruled areas are counted with the aid of a microscope. Since the exact area enclosed by the rulings is known, as is the elevation of the coverslip over the platform, the volume of diluted fluid from which the enumerated cells had settled is also known. The latter would be strictly proportional to the area of the platform which was counted, if the assumption that all cells settled without any lateral shift were correct. Calculation of the concentration of the cells in the original sample then follows the formula:

$$\frac{\text{No. of cells}}{\text{Area}} \times \frac{1}{h} \times \text{Dilution} \times 10^6$$

= Concentration of cells in original sample

where,

Area = (mm)<sup>2</sup> enclosed by the rulings, as used in the particular counting procedure

No. of cells = the number of cells enumerated in the specified area

h = elevation in mm of the coverslip over the platform (usually 0.1 mm)

The specific multiplier factors pertaining to enumeration of red cells, white cells, and platelets are given in laboratory manuals<sup>11,49</sup> and earlier editions of this book.

Critique. Sources of error in the traditional hemocytometer technique are listed in Table 1-2. The assumptions that the cells in question are uniformly distributed per unit volume of diluted fluid in the pipet and that this homogeneity is not disturbed as the fluid is discharged through the narrow stem of the pipet and pulled under the coverslip of the counting chamber by capillary action are not strictly correct. Furthermore, as the cells settle in the counting chamber, some lateral displacement occurs. As a result, the cells enumerated in a given ruled area of the hemocytometer do not necessarily represent those from the overlying volume of fluid and thus an inherent error is created. This is true

**Table 1-2. Sources of Error in Blood Cell Counts Specific for Hemocytometer Technique\***

1. Inadequate shaking of pipet before filling counting chamber.
2. Failure to discard 4 drops from pipet before filling counting chamber.
3. Irregular filling of chamber trapped air bubbles, dust or oil on chamber or coverslip
4. Chamber coverslip not flat (especially important for phase-contrast method platelet counts with  $\approx 1\frac{1}{2}$  thickness coverslip)
5. Inaccurate rulings on chamber
6. Enumeration procedure Too many or too few cells included wrong borders, skipping cells, counting some cells twice
7. Total number of cells enumerated is too low to give statistical confidence in result
8. Error in recording from tally
9. Calculation error, failure to consider actual (non-standard) dilution, or area counted
10. Result entered opposite name of wrong patient

\*Also see Table 1-1

even if the diluting pipet, diluting technique, and hemocytometer rulings were all perfect, which, of course, they are not. If the inherent error of distribution of cells in the hemocytometer were a truly random process, then its effect could be reduced by increasing the sample enumerated, ie, increasing the area used and increasing the minimum number of cells counted in the sample.<sup>5,15,124,142</sup> Taking into consideration the inherent errors of calibration of the pipets and chambers and those of distribution,<sup>95</sup> a formula has been devised which indicates the probable minimum error in the procedure of counting red cells.<sup>6,7,124</sup>

$$C.V. = \pm \sqrt{\frac{8464}{c} + \frac{21.2}{h} + \frac{22.1}{p}}$$

where,

C.V. = one coefficient of variation (see page 19)

c = the number of cells enumerated

h = the number of hemocytometer chambers used

p = the number of pipets used

The formula also applies to enumeration of leukocytes and platelets, except that for the latter the constant in the numerator of the first term is  $10^4$ .

The number of cells counted in the range from 200 to 1000 has the most telling effect on the C.V. Beyond 1000 cells, there is little theoretical benefit from increasing the sample size, because the chamber and pipet errors become predominant.

If two pipets and two chambers are used and a minimum of 500 red cells enumerated, the inherent error results in a true answer lying within  $\pm 11\%$  of the reported result, on 95% of the occasions. If only 100 cells are enumerated (as in a blood sample from a patient with anemia or when a platelet or leukocyte count is made), the corresponding error is about  $\pm 22\%$ . In samples from a patient with anemia, leukopenia, or thrombocytopenia, fewer cells will be enumerated than would otherwise be the case, unless the technician makes compensatory changes in the technique. For example, a 1:10 dilution should be used in place of a 1:20 dilution for leukocyte counts, a 1:50, 1:20, or even lesser dilution for platelet counts; and a 1:100 dilution for red cell counts. A greater than usual area may need to be counted on the hemocytometer. Sometimes, changes in both dilution and area may need to be made.

Clearly, in addition to the above considerations, the technical proficiency of the individual who performs the actual dilutions and counting procedures is of the greatest importance. Idiosyncracies of technique<sup>125</sup> and subconscious bias in counting<sup>15</sup> result in greater reproducibility of blood counts for individual technicians without correspondingly greater accuracy of the results.

The error of a blood-counting procedure<sup>30</sup> which the clinician should normally accept depends upon the clinical implications of the different results created by such laboratory error. An error zone of even  $\pm 20\%$  (two coefficients of variation, 95% confidence limits) in leukocyte counts and platelet counts ordinarily does not have an important impact on clinical interpretation. Hence, hemocytom-

eter methods are acceptable for counting leukocytes and platelets. However, much greater precision is required for detecting and measuring anemia or polycythemia. The centrifuged VPRC and photoelectric hemoglobinometry (cyanmethemoglobin) have a considerably smaller error than that which may be achieved by counting red cells on a hemocytometer; hence, for the detection of anemia or polycythemia, centrifuged VPRC and photoelectric hemoglobinometry have supplanted the hemocytometer method of counting red cells. The red cell count is now primarily obtained for use as the divisor in calculating the corpuscular indices (MCV, MCH). In these calculations, an error zone greater than  $\pm 11\%$  could alter the interpretation of results significantly. Therefore, if the hemocytometer method must be used for counting red cells to determine the corpuscular indices, then painstaking technique (Chapter 3) should be followed.<sup>41</sup> However, electronic methods for enumeration of red cells are preferred since they have the capacity to reduce the error considerably below that of the traditional hemocytometer techniques, even to  $\pm 2\%$ .<sup>21,26</sup> At present, with due regard for technical matters, the most accurate measurements of red cell indices can be achieved by the use of electronic red cell counting (as discussed below), photoelectric hemoglobinometry by the cyanmethemoglobin method, and the determination of the VPRC by the Winrobe macrohematocrit method.

*The examination of a well-prepared, well-stained blood smear by the physician himself when a patient is suspected of having a hematologic disorder is just as important as the physical examination of the patient. This will not only provide important diagnostic information, but it is the physician's best safeguard against laboratory errors. When the experienced physician's interpretation of the stained blood film (page 27) conflicts with the information reported by blood-counting procedures, the wisest course is to have another blood film made and stained, and also to repeat the blood counts, rather than accept one and disregard the other. Not only may*

technical factors lead to error of either interpretation or counting, but there is always the chance of mislabeling of specimens. When properly performed, both blood counts and stained blood films should yield results that agree with and supplement each other. Persistent conflict of data from the two methods must be explained. Error may be one explanation, but may not necessarily be responsible. For example, the interpretation of hypochromia on the blood smear which is not supported by a low MCHC, could be explained by the presence of leptocytes (Chapter 26).

### Electronic Methods

Electronic and automated procedures for enumerating the formed elements in the blood have several advantages over the hemocytometer techniques. Chief among them are a greater precision (reproducibility), reflected in a lower coefficient of variation, and the capacity for completing a large number of determinations quickly and without increasing error due to fatigue. However, the cost of the electronic cell-counting instruments runs into many thousands of dollars (\$2500 to over \$50,000), depending in part upon the numbers of samples processed per hour, the degree of automation, and the number of ancillary measurements performed. Accordingly, these instruments are mainly employed in laboratories where a large number of determinations are to be made each day and where economic factors weigh in their favor. They are also popular in laboratories engaged in research or in clinics requiring the greater precision of blood counts achieved by these instruments when they are properly adjusted and calibrated. Some instruments can also measure cell-size distribution<sup>22,75,121,170</sup> and do so with an accuracy and speed which far surpass the now obsolete manual and visual methods.<sup>94,147</sup> In addition they have also been adapted to quantitate hemagglutination reactions.<sup>16,78,80</sup>

Several different instruments are available and are widely accepted. Almost all employ

transducers which depend upon either the *impedance principle*, or the *dark-field optical principle* for enumerating cells.

### Impedance Principle

This is used in the Celscope, Coulter, and the General Science Corporation Haema-Count systems, to name a few. A regulated constant current is passed between two platinum electrodes immersed in a special, electrically conductive diluent which is selected according to the cell type to be counted. The electrodes are isolated from each other (Fig. 1-3) by an insulator containing a small aperture (60 to 100  $\mu\text{m}$ ). The cells to be enumerated are first diluted with great accuracy and they must be evenly suspended in the diluent fluid. As the suspension is drawn through the aperture, each cell displaces its own volume of the conducting electrolyte solution within the cylindrical aperture. The cells are poorer conductors than the solution. As they pass through the aper-

ture, they individually produce a measurable change in impedance<sup>47</sup> which is very nearly proportionate to their individual volumes.<sup>105</sup> The resulting electrical pulses are amplified and are counted during the time an accurately metered volume of the suspension is drawn through the aperture. Most impulses of "less than threshold value" are attributed to electronic noise, and are rejected after discrimination.

In addition to the particle count per unit volume, a number of other values may be computed electronically from the same measuring process. By coupling the counting instrument to an electronic device for sorting pulses by their amplitude and storing these in a series of registers (multi-channel analyzer), the *cell-size distribution* may be computed, and tabulated or automatically graphed by an X-Y recorder.<sup>22,121,128</sup> Pulse-amplitude summation may be recorded simultaneously with pulse enumeration, and, when the former is divided by the latter electrically, this yields the average pulse size (ie,

Fig. 1-3. Schematic diagram of the impedance type of electronic cell counter (see text, this page). The diluted sample containing the suspended cells moves through the aperture. The impedance is measured by the electrodes. It changes abruptly with each particle that passes through the aperture. The electronic circuitry counts the pulses in relationship to the flow of a metered volume.

mean cell volume, MCV). Furthermore, by taking advantage of the relationship

$$MCV = VPRC \div \text{Number of red cells (RBC)}$$

it is apparent that the "hematocrit" can be computed as the product of the MCV and the number of red cells<sup>10</sup>; and, that the "hematocrit" would be proportionate to the pulse-amplitude summation. Thus, in addition to enumerating white cells, platelets, or red cells, this type of equipment can electrically compute a simulated "hematocrit" and the MCV (Chapter 3) in less than a minute, almost simultaneously with the enumeration, and do so without employing a centrifuge.<sup>40-46</sup> The sources of error in the method are discussed later in this chapter.

A capacitance type of counter (TOA) is similar to the impedance types except that the electrical signal is developed by the change in capacitance resulting from the passage of a particle through the aperture.<sup>52</sup> However, with this instrument the electrical signal is not proportional to the cell size<sup>53</sup> and therefore cannot be used for cell sizing, volume distribution, or electronic simulation of MCV or hematocrit.

### Darkfield Optical Principle<sup>107</sup>

This is used in the Fisher Autocytometer, Technicon Autoanalyzer, and in SMA-4, SMA-7, and Hemolog electronic instruments.

A narrow stream of cells, uniformly suspended in an appropriate diluent, passes the focal point of a microscope-type objective in single file, in a darkfield illumination system<sup>17</sup> (Fig. 1-4). Each cell causes diffraction and forward scattering of the light and the latter is carried by a series of mirrors and lenses to a photomultiplier tube.<sup>126</sup> The image of each cell, falling one at a time upon the tube, alters it from the dark to the illuminated state and thereby generates an electrical (voltage) pulse. The pulse is amplified and counted, in relationship to the delivery of a known volume of diluted cell suspension, as it passes through the counting channel. The pulses in this system are not sufficiently proportional to cell size to readily allow the MCV or the "hematocrit" to be electronically represented from the enumeration data alone. Sources of error in this type of system are discussed below.

Double-scan instruments are a variation of the darkfield type. However, they move a chamber filled with a fixed volume of diluted blood to-and-fro and sideways by means of cams, rather than count a flowing stream of cells.<sup>122</sup> In this design, the slit aperture sweeps over an area of the chamber determined by the number and length of its excursions, the optical magnification, and the slit dimensions. Cells which lie only partially within the field of view, and therefore produce too small a signal to be detected, are

Fig 1-4. Schematic diagram of the operating principle of the darkfield-optical type of electronic blood cell counter. Light from a source lamp is passed through an aperture (not shown) and is focused at the center of the narrow stream in the flow-cell. When a blood cell is not at the focal point, light passing through the cell is stopped at the darkfield disk. When a blood cell is present, light is scattered so that it passes around the disk as illustrated by the three most lateral rays, above and below. The scattered light is collected by a lens and projected through an aperture to a photomultiplier or photodiode light detector. Each cell creates a pulse of light on the detector (see text).

differentiated from background by a second scan at altered slit dimension.<sup>48</sup> The need to fill a chamber with a static volume and the mechanical requirements for chamber movement lend themselves less well to high productivity than do the previously mentioned types of equipment.

USES. The electronic counters may be used to count *leukocytes*<sup>2,70,71,80,141,150</sup> and *platelets*<sup>35,37,54,59,60,68,82,160</sup> if particular adjustments are made in the instrument settings for threshold, aperture current, and signal amplification. The choice of diluent is critical for leukocyte work in order to eliminate interference from red cells; this is discussed below. To count platelets with the impedance type of instruments, interference from red cells is avoided by a preliminary sedimentation step so that only the plasma is diluted and counted.<sup>37</sup> With the darkfield optical type of instrument, platelet counts may be made on whole blood by rendering the red cells of the same refractive index as plasma through the addition of urea solution to the stream of cells prior to entry into the darkfield. Leukocytes are differentiated from platelets by threshold setting and their number is subtracted from the total.<sup>29</sup>

CRITIQUE. The technical superiority of the electronic instruments in enumerating cells of any given sample depends largely upon a far greater sample size than is possible with the hemocytometer. A technician using a hemocytometer might enumerate 500 red cells in a chamber in about five minutes. The electronic counter would enumerate about 50,000 cells from such a specimen in less than half a minute. Counts may be repeated with a C.V.  $\pm 1$  to 2%.<sup>21,128</sup> To reduce the C.V. on a single blood sample to about  $\pm 1\%$  with the hemocytometer technique would require the enumeration of about 50,000 cells and the use of 50 pipets and 50 chambers—a full day's work for one technologist. Avoidance of the error of distribution on a chamber and of the variation in volume from one chamber to the next, accuracy of recording during the actual counting process, and stable performance without fatigue are additional factors favoring the electronic counter.

**Table 1-3. Sources of Error in Blood Cell Counts Specific for Electronic Counters\***

- 1 **INCORRECT DILUENT OR LYSIS AGENT†** for particular instrument
- 2 **EXTRANEOUS PARTICLES IN DILUTING FLUID** (or containers, at any step)
- 3 **PRESENCE OF CELL TYPE WHICH WAS NOT TO BE COUNTED**
- 4 **DESTRUCTION OF CELL TYPE WHICH WAS TO BE COUNTED**
- 5 **ERROR IN METERED DELIVERY OF CELLS AFTER DILUTION** pump, valves, tubing, connections cut-off switch
- 6 **PARTIAL OBSTRUCTION OF APERTURE** (impedance type instrument)
- 7 **COINCIDENCE LOSS**
- 8 **THRESHOLD SETTING** sensitivity or potentiometer setting not determined by proper calibration
- 9 **CARRY-OVER** from one specimen to the next
- 10 **SPURIOUS PULSES FROM SENSING REGION** of equipment due to air bubbles
- 11 **SPURIOUS SIGNALS** from electrical or RF interference
- 12 **INSTABILITY** or intermittent failure of electronic components

\*See also Table 1-1

†Applies to leukocyte and platelet counts

It is often assumed that great accuracy and reproducible performance are inherent properties of sophisticated electronic devices. As a result there is a strong inclination for physicians to accept the results of electronic cell counters as being accurate and beyond question. Not only are those assumptions false, for electronic performance varies with design and component quality, but, in the instance of cell counters, there are considerations beyond the electronic system which have significant bearing on the results. The possibility of electronic malfunction can be evaluated with a simple device.<sup>169</sup> Other potential sources of error in the use of electronic counters are listed in Table 1-3.

Failure to observe all of the precautions mentioned earlier when obtaining the speci-

men of blood could create gross error in the numerical output. Unfortunately, misleading or ambiguous labeling of the patient source, or of the sample number, does occur. This possibility must be kept in mind when the machine output does not correspond with the clinical situation.

Devices for counting particles electronically require greater dilution of the blood than does the hemocytometer technique. Obviously, inadequate precision in making the dilution can negate the accuracy that might have been achieved by the sophisticated device. The method for making the dilution may be critical to the reliability of the overall results. Either micropipets, calibrated within  $\pm 1\%$  error, or commercially available low-cost capillaries which fill automatically with an accuracy of  $\pm 1.25\%$  may be used in conjunction with pre-dispensed diluent. Properly calibrated semi-automatic dilutors<sup>38</sup> (which are moderately expensive) are another alternative to provide the accuracy warranted in the dilution step for electronic cell counters. In the Coulter Model S the dilution system is an integral part of the apparatus. The Hema-Aliquanter is said to be more accurate than standard pipets and less costly than other semi-automatic dilutors.<sup>39</sup>

In the Coulter counting systems, an error in diluting will not only create an error in the enumerated red cell count, but also it will produce an error in the same direction in the "hematocrit" which is computed by the automatic accessory for the Models B, D, and F, or the Model S; and in the MCV, if that is calculated by the technician from the electronic red cell count and the centrifugal VPRC.<sup>40,46</sup> However, the MCV which is computed automatically by the Model S, or the accessory for the Models B, D, or F, is not affected by erroneous dilution, although it is influenced by the threshold setting.

Leaky valves or other faults in the metering system which delivers the diluted samples to the sensing region can produce erroneous results, since standardized counting volume (or flow rate, at fixed counting time) is required.

The choice of diluent is also important.

For red cell counts an isotonic solution is needed so as not to alter cell volume. Isotonic saline alone is satisfactory if only counting is done.<sup>21</sup> If cell volumes, MCV, or "hematocrit" is to be automatically computed or cell sizing is to be done, a buffered medium is needed to avoid notable swelling of cells<sup>45,115,137</sup> which otherwise will occur with time.<sup>22</sup> A solution consisting of 0.17 M NaCl and 0.3 M tris(hydroxymethyl)aminomethane (Tris, THAM) buffered to pH 7.4 with HCl, 95:5 (v/v) is perfectly satisfactory.<sup>46</sup> It is easier to prepare and keeps better than does the more elaborate Eagle's salt-dextrose medium. The latter had been shown to give a stable cell volume-distribution curve, very similar to that of red cells suspended in plasma,<sup>22</sup> and had been widely used for that purpose. The solutions recommended by the instrument manufacturers (eg, Isoton) are also satisfactory and have the advantage of being filtered by the manufacturer to remove microscopic particles.

Selection of a diluent for counting leukocytes is very critical. Red cells must be lysed to avoid interfering counts. If destruction of leukocytes occurs in addition to lysis of red cells, spuriously low leukocyte counts result. Erroneous high counts may be produced if there are residual erythrocytes or stroma particles. Furthermore, with some diluents the value of the machine count varies with the interval after the dilution is made. Triton-X 100,<sup>2</sup> saponin,<sup>150</sup> 0.1 N hydrochloric acid,<sup>142</sup> and cetyltrimethylammonium bromide (Cetrimide, B.P.; Cetavlon<sup>TM</sup>)<sup>85,166</sup> have been advised as diluents which also lyse erythrocytes. Cetrimide with acetic acid had been preferred<sup>144</sup> because its stromatolytic action is much more rapid and more complete than that of saponin. The latter is totally unsatisfactory for mouse blood.

Cetrimide-citrate-saline with acetic acid<sup>50</sup> is even better because the addition of citrate abolishes the cytolytic effects of cetrimide on leukocytes and allows constant leukocyte counts on electronic instruments for as long as 24 hours after the dilution is made. However, occasional loss of lymphocytes occurs in blood from chronic lymphocytic leu-

kemia,<sup>138</sup> giving a falsely lower leukocyte count.<sup>57</sup> Substitution of ethylhexadecyldimethylammonium bromide (EHDA) (Eastman Kodak, Rochester, N.Y.) for cetyltrimethylammonium bromide in the citrate-saline, acetic acid formula<sup>70</sup> produced as good or better results with both the Coulter Model B and Fisher Autocytometer, and we recommend it for leukocyte counting. In chronic lymphocytic leukemia, the results compared well with hemocytometer techniques and loss of cells was not a problem.

Normally, a 1:500 dilution is made. When leukopenia is suspected or when fewer than 4000 leukocytes are enumerated in the volume (usually 0.5 ml) of blood which is counted at a 1:500 dilution, a 1:100 dilution is made by using a more concentrated ("low-count") diluent. The additional EHDA detergent in the latter formulation assures complete lysis of the additional quantity of red cells. The same solution is used, for the same reason, when counting polycythemic blood.

Of course, all diluents must be free of *extraneous particles* prior to use.<sup>52</sup> A simple filtration apparatus with triacetate filters such as the Millipore or Mettracel type with 0.45  $\mu$ m pores should be used. Commercial, suitably filtered diluent may be obtained from the instrument manufacturers.

*Coincidence loss* occurs when two cells enter the sensing zone of the apparatus simultaneously, or the second enters immediately after the first but in the brief refractory period as the signal from the first is developed. In both instances, only one cell is counted. In the impedance type of instruments, if cell sizing is being done, one large cell is recorded in place of two smaller cells. This error is a direct function of the concentration of cells in the diluent and the volume of the sensing region of the apparatus.<sup>128</sup> Greater dilutions reduce the problem, as do apertures of smaller diameter (60  $\mu$ m vs 100  $\mu$ m) and depth. Correction tables are supplied by manufacturers and these must be used to compensate for coincidence loss, unless the apparatus does so automatically, as, for example, the Coulter Model S and the

Fisher Autocytometer. Artifacts of cell size and volume distribution curves are related to aperture dimensions,<sup>31</sup> but asymmetry of volume distribution curves may describe a real phenomenon.<sup>3,120,171</sup> Antibody-coated cells also result in spurious macrocytosis.<sup>25</sup>

A small amount of diluent containing cells remains in the system after each count. This *carry-over* may be more significant in the Fisher Autocytometer, Technicon Autoanalyzer, and SMA series than in other instruments, and in Coulter Model S than in other Coulter models. Therefore, when the results of two successive samples have widely separated values, particularly in leukocyte counts where values of abnormal samples might vary by as much as a factor of 100 or more from each other, it is best to repeat the second count to ascertain its correct value. Normally, leukocytes are so infrequent compared with red cells that their presence may be disregarded when performing a red cell count. In leukemia, when leukocytosis and anemia are both present, a correction may need to be made.

It is clear that, in all electronic counters, some signals may be generated from the apparatus itself ("electrical noise") and that a highly favorable ratio of true *signal to noise* is needed for accurate counting. Low-amplitude noise can be discounted with high efficiency by discriminator circuits, if the instrument is electronically stable. Random entry of extraneous large signals sometimes results from sudden line-voltage fluctuations, as when other apparatus or electric motors are turned on and off. Electrical isolation transformers and voltage regulation devices may be needed. Radio-frequency pulses (RF) from electrical apparatus, flickering fluorescent lamps, and sparking motor brushes may sometimes be detected as "counts" by these counters. Additional RF shielding may be required to eliminate them. Inspection of the oscilloscope screen on the Coulter usually, but not always, indicates the occurrence of RF interference.

Setting the lower *threshold* eliminates spurious electronic and RF pulses of low amplitude and can also be used to reject

Fig 1-5 The relationship of the 'threshold' setting value to the 'count' enumerated by a Coulter Counter. Clearly a wide variance in the 'count' can be obtained depending on the value selected. The low slope of the 'plateau' represents the small-size end of the distribution of cell sizes. Threshold settings are usually chosen in this region, characterized by the smallest variance in 'count' for a given error in adjustment, although there is no assurance of 'accuracy' by taking this approach. The placement of the curve is a function of the aperture current setting (ACS) and amplification. (From Gagon et al,<sup>70</sup> courtesy of authors and Williams & Wilkins Co)

pulses from particles smaller than those of primary interest. For example, platelets may be disregarded when counting the larger red cells simply because they are so much smaller in size. However, if the threshold is raised too high (for example, in the Coulter Model A or B), the smaller red cells would not be included and a falsely low red cell count would result (Fig. 1-5). If the MCV were calculated from that value, it would be falsely high. This error is most likely to occur when very microcytic red cells are counted, as in severe iron-deficiency anemia, even though perfectly satisfactory results might be obtained when counting red cells whose MCV and cell size or distribution were normal or greater than normal. In fact, by setting the threshold value higher or lower, one can generate almost any value<sup>73</sup> for the instrument's "red cell count." Since cells vary in size even in healthy persons, in a nearly gaussian distribution in the case of red cells,<sup>22,34</sup> raising the threshold of a Coulter counter can pro-

gressively lower the count by excluding cells.<sup>73</sup> Lowering the threshold can spuriously raise the count by including non-red cell particles and even the electrical noise impulses.

Calibration of the instrument is therefore of prime importance and relates to threshold values and discriminator and potentiometer settings, even if the latter were set at the factory. Since, with variation of the potentiometer settings, virtually any printed output can be produced on the Coulter Model S, this instrument, as well as the others, must be calibrated by the user<sup>24,36,117</sup> to assure its accuracy. Accuracy is the quality that describes proximity of a measurement to the "true" or "real" value of the measured item. Reproducibility, or precision, is the measure of the closeness together of measurements of the same item upon replicate determinations. An incorrectly calibrated instrument, otherwise functioning well and with high precision, would yield the same wrong answer

every time a replicate of a sample was tested. The user must not mistake precision for accuracy. The precision usually reported at  $\pm 1$  or 2 C.V. represents the usual (minimum) error range to be expected from isolated determinations, even if the mean of a series of replicates were exactly the "true" value. One coefficient of variation (C.V.) is the ratio of the standard deviation (S.D.) to the mean ( $\bar{X}$ ), expressed as a percent. That is, C.V. (%) =  $[(S.D.) \div \bar{X}] 100$ . For example, precision of  $\pm 2\%$  (2 C.V.) means that 95% of the time the reported value will be not more than  $\pm 2\%$  away from the true value. Stated in another way, 95% of the time the true value would lie within  $\pm 2\%$  of the reported value. Statements of instrument performance or data often appear in journals, books, and advertising as  $A \pm b$ , without identifying whether "b" signifies  $\pm 1$  S.D.,  $\pm 2$  S.D.,  $\pm 1$  S.E.,  $\pm 2$  S.E., or some other value. Such statements are too vague to be meaningful<sup>62</sup> but are all too common in the literature of electronic counters.

Quality-control specimens must be run on each instrument under operational conditions<sup>58,117,167</sup> to assure continuing satisfactory performance. Unfortunately, an absolute reference standard is lacking for enumerative procedures.<sup>64,105,135</sup> To obtain the "true" value on a sample of blood, recourse must ultimately be had to many replicate determinations by hemocytometer techniques, which, paradoxically, are less precise than the electronic method one wishes to calibrate.<sup>24</sup> Since there is a 95% probability that the true mean lies within  $\pm 2$  S.E. of the experimental mean, and the S.E. =  $S.D. \div (N-1)^{1/2}$  (where "S.D." is the standard deviation of a series of measurements and "N" is the number of measurements in the series), it becomes possible to define the true value for cell counts, within about  $\pm 2\%$ , by performing a series of about 17 to 26 measurements. Laboratory reference standards which are prepared from blood and are stable for 14 to 28 days may be used for daily standardization of automatic instruments. These are available commercially, or may be prepared from formalin-<sup>132</sup> or glutaraldehyde-treated red cells,<sup>116</sup> or by

processing blood by a method incorporating adenine, citrate, phosphate, dextrose, hydrocortisone, and promethazine.<sup>177</sup> Standards for leukocytes<sup>113</sup> and platelets<sup>134</sup> have been described. Refrigerated specimens may be carried forward daily as another type of verification.<sup>27</sup>

### *Multiple Parameter Automated Blood-Counting Machines*

#### *Principles*

Automation of the most commonly requested hematologic blood tests has been combined into single instruments to conserve time and labor and reduce costs in laboratories with a large volume of daily work. Widely used in large hospital laboratories are the Coulter Model S<sup>TM</sup> and Technicon SMA-7A<sup>TM</sup>. These combine automatic sample dilution with their individual type of red and white cell counting apparatus described above, and also perform hemoglobinometry photoelectrically as cyanmethemoglobin.<sup>24,71,76,103,136,157,159</sup> A computed value for "hematocrit" is produced by the Coulter instrument, and the red cell indices are further computed. Digital output for hemoglobin concentration, "hematocrit," RBC, WBC, MCV, MCH, MCHC is produced at the rate of two to three samples per minute. The SMA-7A performs the same measurements, except it estimates "hematocrit" from the electrical conductivity of the whole blood (conductivity cell volume, CCV) and computes the red cell indices with that value. The Fisher Hem-Alyzer<sup>TM</sup> measures the red and white blood cells by using the dark field-light scattering principle, and measures hemoglobin as cyanmethemoglobin.<sup>111</sup> "Hematocrit" is not attempted and red cell indices are not calculated. The Technicon Corporation's Hemolog<sup>TM</sup> performs blood counts and the CCV as does the SMA-7A. It also does a platelet count<sup>29</sup> and adds a centrifuge device continuously operating at 23,000X G. In the latter, the packed cell-plasma interface is detected photoelectrically, and followed mechanically to esti-

mate the "hematocrit."<sup>149</sup> Other parts of this instrument measure the prothrombin time and the partial thromboplastin time.

**CRITIQUE.** In general, good precision in cell counting and hemoglobinometry (CV,  $\pm 1-2\%$ ) is achieved by combining automatic dilution with efficient mensuration. Carry-over of 2 to 7% in the Coulter Model S may produce 5%<sup>24</sup> or even 25% error when a true sample value is less than one third of its counterpart in the immediately preceding sample. For example, in one published report, when a sample with a WBC of  $8.4 \times 10^9/l$  was followed by one of  $1.5 \times 10^9/l$ , the instrument reported  $2.0 \times 10^9/l$  for the latter.<sup>157</sup> Unless the operator is alert for such sequences and runs the low-count sample again, day-to-day precision and accuracy will be adversely affected in certain patients with low blood counts, whereas performance of the instrument will remain good in other patients. Leukocyte counts greater than  $50.0 \times 10^9/l$  interfere with hemoglobinometry and are rejected by the instrument. Measurement of the MCV and "hematocrit" are good with the Coulter Model S and are not adversely affected by too low a ratio of blood to dry anticoagulant in the sample.<sup>28</sup> As in the case of the attachments for the Coulter Models B and F, the computed MCV is independent of dilution error, but is susceptible to error in setting the lower threshold and instrument calibration.

The "hematocrit" as computed by the SMA-7A is also termed the *CCV* (conductivity cell volume). This is based on the principle—published in 1898<sup>31,162</sup>—that the electrical conductivity of the blood is an inverse function of the volume of the packed cells.<sup>66,67,74,161</sup> Refinements in technique<sup>100,127</sup> and engineering have produced an instrument which performs well with normal blood.<sup>77,100</sup> However, erroneously low values result when insufficient blood from venipuncture is put into the collection tube, giving a ratio of dry anticoagulant to blood exceeding 1.0 mg EDTA/ml blood.<sup>112</sup> Furthermore, calibration which is performed with two concentrations of potassium chloride has been reported to be non-linear,<sup>100</sup>

and abnormalities in serum proteins and electrolytes, such as those which occur in patients with significant illnesses, introduce additional error to the technique, as do lipemia and marked leukocytosis.<sup>53</sup> Consequently, in certain samples the reported "hematocrit" (CCV) and the machine-calculated MCV may be erroneously low, whereas the MCHC will be erroneously high.<sup>75,76</sup> The physician must be particularly alert in interpreting such data from this instrument, because diagnostic conclusions run the risk of error. The Hemalog™, manufactured by the same company that produces the SMA-7A, has an automatic centrifugal hematocrit in addition to the CCV device and other features of the SMA-7A. An independent appraisal of the performance of this augmented instrument has not been published.

Differential leukocyte counts can be made by machine by three different methods. These are (1) analysis of cell size distribution; (2) computerized pattern-recognition of stained cells; and (3) analysis of relative light scattering and light absorption by leukocytes after histochemical reactions.

Reliable differentiation of lymphocytes from neutrophils and monocytes, and also from erythrocytes, has been accomplished in dilute suspensions by a multiple-channel analysis of the size distribution among 100,000 cells, as determined by an impedance type of electronic particle counter.<sup>139,176</sup> The preliminary procedures required for separating leukocyte-rich plasma from whole blood, and the insensitivity of the method for differentiation of granulocytes from monocytes, limit its practical application.

The Cellscan-Glopr™ mimics human visual identification procedures by computer-TV image processing. It automatically operates a microscope substage to find, frame, and focus leukocytes on the stained blood film. Illuminating with yellow light, it scans the image point by point and quantitates density with a high-speed special-purpose computer and Golay logic processor. It then repeats the process with green light. Each cell is classified by computer comparison with

previously analyzed stereotypes of neutrophils, monocytes, lymphocytes, and other blood cells.<sup>96</sup> The criteria for differentiation are: cell size, cell shape, and the differential absorption of light by the cytoplasm and its granules at the two wavelengths used; the total area of the nucleus and the presence of concavities, lobes, and fine structure within it. The computer has been programmed to separate up to eight cell types.<sup>96,146</sup> Although this system has the potential of most closely duplicating human interpretation of the blood film, its speed, precision, and accuracy remain to be established in extended trials. However, since the theory of cell recognition by computer is well established<sup>173a,173c</sup> and image processing by computers after analog to digital conversion has been used successfully in a number of applications,<sup>3b,173b</sup> including some in hematology,<sup>97a,173a</sup> the prospects for accurate results with this method are good. Furthermore, computer programs have been written for automatically developing the classification algorithms for the computer's decision-making process from an operator's decisions as he classifies cells.<sup>3a</sup> This technique will greatly simplify further applications of this method.

The LARC™ (Leukocyte Automatic Recognition Computer) is an instrument that performs differential leukocyte counts by computerized pattern recognition.<sup>129a</sup> In about one minute the LARC locates 100 leukocytes by a patterned search procedure of a Wright-stained slide of a blood film, and classifies the cells into one of seven groups: band neutrophils, segmented neutrophils, lymphocytes, monocytes, eosinophils, basophils, and the category "others," representing cells that could not be identified as belonging to the foregoing groups. Then, by using the computer's record of the (x,y) coordinates for each of the cells classed as "other," those cells are, in turn, automatically brought into the field of view of the system's binocular microscope for their visual identification by the operator. The computed differential count is automatically adjusted according to the outcome of the operator's classification of those cells. When only normal cell types are

present, definitive classification will fail for about 5% of the cells if the blood films are made on glass slides by using a special centrifugal spreader that the manufacturer claims will produce more even blood films and more uniform distribution of leukocytes, with less cell destruction, than would otherwise be possible.<sup>128a</sup> A preliminary report of the results of a clinical trial with this instrument has been made.<sup>167a</sup> For the screening of routine hospital or laboratory blood films by leukocyte differential counting, the LARC competes favorably against a technologist for accuracy while surpassing the technologist in speed. However, the role of the LARC seems to be to augment the technologist's performance, rather than to replace his evaluation of the blood film, since identification of "other" cells and the description of the morphologic appearance of the erythrocytes and platelets, any one of which may be crucial to a given case, still require human intervention. Greater clinical trial than that presently experienced will be required to determine whether this machine's contribution to the evaluation of the blood will be medically satisfactory and economically advantageous.

The Hemalog-D (trademark of the Technicon Corporation) is a commercially available instrument which automatically determines the leukocyte differential count in a flowing stream of cells at the rate of 60 samples per hour.<sup>154</sup> Whole blood samples of 0.52 ml are diluted, fixed, and then subjected to specific histochemical reactions in each of three simultaneously operating channels. Interfering signals due to erythrocytes are avoided by hemolysis and by the addition of propylene glycol to render the residual stroma translucent. By means of an improved "sheathed" stream control, a single file of leukocytes passes the light beam focused at the flow cell in a system akin to the darkfield light-scattering instrument described earlier. All leukocytes scatter the light forward, through a beam splitter and beyond the darkfield stop disk, to the first photodiode. Cells giving a positive histochemical reaction in a given channel also absorb light, and this is detected in the split beam by the second

photodiode. Pulse amplitude analysis for both light scattering and light absorbance in a given channel provides a two-dimensional vector "description" of each cell which, together with the proper thresholds, is claimed to be unique for each cell type. The three channels for differential histochemical reactions are: (1) peroxidase, at pH 3.8 with 4-chloro-1-naphthol, which stains *eosinophils* deeply and *neutrophils* lightly; (2) lipase, at pH 6.25 in a caccodylate buffer (to block interference from plasma lipase) with  $\alpha$ -naphthyl butyrate as a substrate and hexazonium pararosanilin as the stain for *monocytes*; (3) toluidine blue stain, for *basophils*. In a given channel, within the limits of the upper and lower threshold values, the proportion of cells absorbing light relative to the total number of cells enumerated simultaneously by forward light scattering yields the percentage of the specified cell type in the "differential." Small lymphocytes are determined from the peroxidase channel as the proportion of cells not reacting, hence not absorbing, light (ie, "agranulocytes"); monocytes and platelets are excluded by upper and lower threshold settings, respectively. The sum of the percentage represented by monocytes, small lymphocytes, basophils, eosinophils, and neutrophils, determined by histochemical reaction and pulse-amplitude analysis, is claimed to ordinarily equal, or very nearly equal, 100%. Large lymphocytes, leukoblasts, and other cells which have failed to take the histochemical stains are grouped in the category designated "unclassified cells," with the value derived by subtracting the sum of lymphocytes and monocytes from the "total agranulocyte count" determined in the peroxidase channel.

Thus system uses the combination of histochemical distinctions among leukocytes and cell sizing in a sophisticated optical-electronic system for differential leukocyte counts. The automated system enumerates 10,000 leukocytes in each of three channels for the primary data, whereas the conventional, visual differential counting method classifies only 100 or 200 cells. Whether the large number of cells enumerated will significantly enhance

precision, as has been suggested,<sup>154</sup> not only depends upon the replicability of instrument performance and analysis, but also upon how well this new method for classifying leukocytes compares with the conventional criteria both for patients with nonhematologic disorders and the more challenging patients with abnormal leukocytes. The ultimate usefulness of the instrument which undertakes routine processing of all blood specimens in a large hospital or independent laboratory will depend upon its sensitivity in detecting abnormal cells from among the blood samples from many patients with various diseases. Until favorable performance is established by independent competent trial, conventional procedures for examination of the stained blood film must be followed. Even if suitable accuracy in the automated determination of the differential leukocyte count is proven, the physician must avoid the pitfall of considering this determination as a substitute for the microscopic examination of the blood film. Hemalog D makes no pretense at describing qualitative changes in red cell and platelet morphology, which are important elements of the examination of the blood film. Furthermore, cells classed as "unknowns" by the machine may be of great diagnostic significance and require visual identification and interpretation.

Standardization is essential for even the most precise method, if accurate ("true") results are to be obtained. The impressive reproducibility of results from automated blood-counting machines can lead an observer to the conclusion that these instruments are more accurate than other, less sophisticated, semi-automated, or even manual methods for blood counting, even when the results of the multi-parameter instrument are inaccurate owing to inadequate or infrequent calibration and standardization. Nationwide, interlaboratory quality-control studies have shown serious discrepancies in results with electronic counters, even when standards were sent to the participating hospital laboratories, along with the "unknown" samples.<sup>117</sup>

Excellent standardization of hemoglobinometry<sup>61</sup> is available for the instruments that

measure cyanmethemoglobin. On the other hand, a comparable, stable, absolute reference is not available for particle-counting and cell-volume computation. Pollen grains,<sup>69</sup> latex particles,<sup>155</sup> sodium fluoride-treated yeast cells,<sup>113</sup> preserved blood,<sup>177</sup> and fixed red cells<sup>132</sup> or whole blood<sup>116</sup> have been proposed as intermediate reference standards for comparison in a given laboratory from day to day, and among different laboratories. These still do not represent a primary standard, and validation of reference standards remains a significant, unresolved problem. Present attempts at standardization require comparison with still other instruments or, eventually, the less precise but traditional reference point of manual hemocytometer techniques. In the latter, one should not lose sight of the fact that 17 to 26 replicate counts may be required to reduce the zone of uncertainty about reported results to  $\pm 2\%$  for one standard error. The laboratory which attempts to adjust or standardize an electronic counter with only a single pair of hemocytometer counts, no matter how closely the two agree, or with commercial standards of unproven stability or accuracy, is risking significant error. Carrying forward refrigerated EDTA blood samples from one day to the next serves as a simple but useful quality-control feature for the precision and stability of instruments in the automated laboratory,<sup>27</sup> but does not establish the accuracy of the results.

The physician who interprets results of blood counts must select a laboratory to serve him with knowledge of its accuracy, precision, and quality-control procedures. Unless these qualifications are satisfactory, spurious and variable results may mislead him. A more serious consequence of poor laboratory performance may be the physician's condemnation of established rules and procedures for diagnosis and choice of therapy, when in reality faulty laboratory data were responsible for his erroneous conclusions and actions. Lack of confidence in the morphologic classification of anemia (Chapter 13) often may be traced to reliance upon faulty laboratory data. Throughout his work, the physi-

cian must keep foremost in his mind the understanding that the validity of any information processing procedure, carried out by himself or by a laboratory computer,<sup>23</sup> is wholly dependent upon the validity of the data input. This dependence was recognized in reference to the solution of diagnostic problems in clinical hematology long before it was popularized by modern-day, sophisticated computer operations, with the aphorism: GIGO (garbage in, garbage out).

In summary, electronic cell-counting instruments have the capacity to reduce the error of the blood-counting procedures (Table 1-4) to  $\pm 1\%$  (1 C.V.). However, automation<sup>16,24,33,36,55,56,135</sup> alone, in the absence of strict calibration and quality-control supervision,<sup>58</sup> can produce inaccurate data ad infinitum. The physician must avoid the trap of accepting the output values of automated instruments without the certain knowledge that the correct control procedures are enforced by the laboratory director. This problem has been reviewed in depth.<sup>24,36</sup>

### Examination of Blood by Microscopy

Qualitative evaluation of the morphologic features of the erythrocytes, leukocytes, and platelets by examination of blood films can

**Table 1-4. Accuracy of Blood Counting Procedures**

(Automatic dilutors and electronic cell counters compared with traditional hemocytometer method)

METHOD CELL COUNTED	Two Coefficients of Variation	
	Hemocytometer <sup>1,3</sup>	Electronic <sup>2,4</sup>
Red Cell	$\pm 11\%$	$\pm 3\%$
White cell	$\pm 16\%$	$\pm 4\%$
Platelet	$\pm 22\%$	$\pm 7.6\%^5$

1 Minimal error

2 Usual error

5 The error may be much greater when the platelet count is less than  $35 \times 10^9/l$  or more than  $450 \times 10^9/l$

contribute more toward the diagnosis of conditions which affect the blood, and do so more often, than can any other single laboratory procedure. In addition, parasitemia (malaria, microfilaria) and, rarely, evidences of bacteremia may be found. Three techniques may be used: fixed, polychrome-stained films; wet preparations, examined by phase-contrast microscopy; and wet films, examined by the supra-vital staining method, often in conjunction with phase contrast. Two special methods use electron microscopy: thin section (transmission) and scanning. Electron microscopy is usually reserved for research applications, because of its complexity and expense and the limited occasions upon which it might contribute more to the clinical situation than would standard techniques.

Most widely practiced is the interpretation of the fixed, and stained, *thin blood film*. A valid interpretation depends upon successful completion of three elements: preparation, staining, and examination. The first two are usually the responsibility of technologists rather than physicians. However, they are discussed here because so much depends on their quality and, if problems arise, the hematologist may be severely hampered in his work unless he can resolve them. The techniques are so simple that it is practical, when his work does not warrant the expense of a fully qualified technologist, for the physician to train an office assistant whom he can supervise, rather than forego the opportunity of examining blood films himself in his office. Whether the physician examines the blood films made in his own office, or those made elsewhere, and even when considering reports from technologists and other physicians, it is advantageous to keep in mind the factors which affect the quality of the results.

#### *Preparation of Blood Films*

Films made on coverglasses are preferable, in our opinion, to those made on slides, primarily because a much greater proportion of the blood on the film is technically suitable for examination. Irregular distribu-

tion of leukocytes and platelets occurs on slides,<sup>49,123,131</sup> and it is difficult and sometimes simply not possible to examine the entire slide adequately to determine if the thin zone at the end is representative of the entire specimen and is a reliable basis for interpretation. Sometimes most of the platelets are clustered at the end of the slide where the film is too thick for evaluation, so that the remainder suggests thrombocytopenia. Nevertheless, satisfactory preparations can sometimes be made on slides and some experts prefer them to coverglasses.<sup>49</sup> This is mainly because slides are less difficult to clean than coverglasses and also, being less fragile, they require less care in handling. Laboratories geared toward automation point out that a number of automatic slide-staining machines can work with glass slides<sup>133</sup> whereas only some brands can stain coverglasses.<sup>24,51</sup>

#### *Coverglass Technique*

A good grade of flat, number 1½, square (22 × 22 mm) coverglasses, 0.13 to 0.17 mm thick, are required. They must be free of grease, lint, and dust, and be scrupulously clean; otherwise the blood will not spread and the smear will be totally useless. Rarely, brands are so clean that they may be adequately prepared simply by wiping them with a lint-free cloth or finely woven paper, provided one's hands are first washed free of natural oils and the coverglasses are handled only by their edges. Usually it is necessary to first clean the coverglasses with a detergent and water, then rinse them with hot water, distilled water, and, finally, 95% alcohol. They are then wiped as noted above, and stored in a clean, sealed box. Plastic cover-slips which are "unwetttable" are not suitable.

Details of the procedure are described in earlier editions of this book, and in a manual of laboratory hematology.<sup>41</sup> The chief points to keep in mind are: (1) use a small drop of blood, only 2 to 3 mm in diameter, taken either from a stylet wound, as described earlier (page 6), or from the syringe or needle tip used in venipuncture immediately after the venipuncture has been performed (anti-

Fig 1-6. The preparation of blood films on coverglasses. Notice how the coverglasses are held in (1). They are crossed in (3) to form an eight pointed figure, and the weight of the upper coverglass spreads the droplet of blood. After about two seconds, opposite edges of the upper and lower coverslips are grasped and they are gently but quickly pulled apart with a motion parallel to their flat surfaces. Care must be taken not to lift them apart. (From Haden, *Clinical Laboratory Methods*, courtesy of C. V. Mosby Co.)

coagulants are not to be used as they will alter the morphologic appearance); (2) hold the coverglasses only by their edges, placing one crosswise over the other, and allow the blood to spread between them for about two seconds; (3) quickly but gently separate the coverglasses by pulling them laterally, in opposite directions to one another but in the plane of the spreading film, just before the film reaches the edges (Fig. 1-6) (do not squeeze or lift the coverglasses from one another); (4) quickly air-dry the films, either by placing them face up on a clean surface if the humidity is low, or by moving them

through the air while holding them by their edges with your fingertips.

If the procedure has been carried out successfully, the blood will be spread evenly and there will be neither holes nor thick areas in the preparation. A multicolored sheen will be seen on the surface of the dried, unstained film if light glances off from it at the proper angle, for the thin layer of closely fitting cells acts like a diffraction grating. Later, under the microscope, after staining, the red cells will be seen next to each other, but neither overlapping, nor in rouleau formation, and central pallor will be visible; lymphocytes

will have a readily distinguished cytoplasm, rather than a minimal zone bearing closely on the nucleus as occurs in thick films or those which dry too slowly.

### Slide Technique

The slides must be clean, as noted above, but often not as painstaking a technique is followed as that used for coverslips. Certain brands are suitable as cleaned by the manufacturer, when delivered in cellophane-wrapped and sealed boxes. A somewhat larger drop of blood than that used on cover-glasses is placed on one end of the surface of a slide. It is spread by means of another slide held at about a 30-degree angle to the first slide, and placed at first slightly in front of the drop and then moved back until the drop spreads out at the interface. The spreader is then pushed forward at an even, moderately rapid rate. Faster movement produces thicker but more even films. Centrifugal devices which make blood films are now available. A device has been manufactured to concentrate cells from a suspension onto a microscope slide.<sup>172</sup> The criteria for satisfactory films are the same as noted above. Drying is accomplished as with cover-glasses or, taking advantage of their greater weight, the slides may be placed on a surface and fanned. Fixation occurs during the first minute of staining if the stain, eg, Wright's, contains absolute alcohol.

### Staining

Several modifications of the Romanowsky method of staining are used. The most popular stains are Wright's and the May-Grünwald-Giemsa. These stains for blood smears have as their base a "polychromed" methylene blue, which is metachromatic.<sup>118</sup> Alkalization and subsequent addition of eosin (Malachowski 1891) have replaced the original method which required old, moldy methylene blue. In Giemsa's stain, "methylene blue azure" is added to a mixture of methylene blue and eosin.<sup>164</sup> Details of the staining technique are given in earlier edi-

tions of this book and elsewhere.<sup>41</sup> A properly stained film will appear pink to the unaided eye. Microscopically, the erythrocytes will appear to be pinkish-orange in color, the nuclei of the leukocytes purplish-blue, and neutrophil cytoplasm tannish with violet-pink or lilac granules, while eosinophil granules will be a bright orange-red. When Wright's stain is used, if the whole film is *too blue* and the red cells are stained blue or green, the trouble may be due to (1) too prolonged a staining time, (2) too alkaline a buffer, (3) too little washing after staining, or (4) too thick a smear. To improve the color, less stain or more diluent may be used, or the length of time employed for staining may be decreased and that for washing increased. To counteract the effect of an excess of alkali in the stain, some acetic acid may be added. Sometimes the stain is improved by diluting it with an equal part of absolute methanol. If the stain is *too red*, the nuclei of the leukocytes are pale blue, erythrocytes are bright red, and eosinophil granules stain a brilliant red-orange. This may be due to (1) excessive acidity of the stain or the buffer, (2) too short a staining time, or (3) excessive washing. The buffer must be controlled between pH 6.4 and 6.7. The choice is made according to the color balance desired on the smear. For best results, staining and buffer times must be established for each batch of stain. The concentration of the dyes in Wright's stain is continually changing, owing to progressive oxidizing action in the alkaline solution. Other problems are the loss of methanol from the stain due to evaporation and the acquisition of water vapor by the hygroscopic absolute methanol in the stain. For these reasons, bottles of stain must be kept tightly closed. Artifacts which simulate hypochromic red cells may be produced by water in the Wright's stain.<sup>14</sup> After the buffer has been on the smear for the required time, if one is to avoid leaving precipitates on the surface of the film, the coverglasses must be flooded with water rather than tilted to rid them of stain. Precipitated stain obscures details, may be confused with cocciform bacteria, and can simulate red cell inclusions.

## Examination

The microscopic examination of the blood film can provide more useful and important information for the evaluation of hematologic problems than can any other single test. The blood smear should be examined for more than the differential leukocyte count. Astute deductions regarding the concentration of leukocytes and platelets in the blood can be made, thus guarding against major faults in the reported counts; also the red cell and platelet morphology may be assessed and a search can be made for foreign elements. A systematic approach is important.

First, the blood film should be examined, at about 100X magnification (low power), for its adequacy of cell distribution and staining and for freedom from artifacts. We make it a practice to examine at least two coverglass films from any single specimen. The important features of cell distribution are illustrated in Figure 1-7. Signs of a poor film are: disruption of leukocytes, overlapping or aggregated red cells, or areas almost entirely comprised of cells with (1) uniform loss of central pallor, (2) polygonal shapes—excepting characteristic poikilocytes (eg, sickle cells, helmet cells), and (3) "spherocytic" appearance. True spherocytes, in contrast to artifacts, usually show some variation in central pallor and are usually smaller than normal cells, whereas artifacts are larger.

Fig 1-7. The arrangement of red and white blood cells in a correctly made blood film for microscopic examination

If the preparation is not satisfactory, one should not proceed further. Other stained films should be examined, or new preparations should be made. Quite misleading impressions can be gained from attempts at interpretation of substandard blood films. This fact is not fully appreciated by technologists and physicians who deal mainly with routine blood examinations, for, by chance alone in view of their material, their error ratio will be low. Nevertheless, an error of omission, or an incorrect interpretation, places an additional burden on the patient and his physician. From the patient's point of view, an error which could have been readily avoided is not easily forgiven. In laboratories with a heavy work load, a conflict of interest is created for the technologist who is concerned with the adequacy of a given preparation and who is considering devoting additional time to making a new preparation. It is up to the physician in charge of the laboratory to see that quality is not sacrificed for speed. It is a good practice to save blood films, even in routine laboratories where they may be kept for at least two weeks, to allow an opportunity for further evaluation in retrospect and to serve as a quality control measure in the event surprising or conflicting findings appear later. In patients with hematologic problems, it is essential that the blood film be examined by a qualified physician or his consultant.

If the blood films are satisfactory, the examiner should estimate the leukocyte count by surveying many fields, keeping in mind the normal situation. The findings should be compared with the reported count when it becomes available.

Next, under about 1000X magnification (switching to the high-power, oil-immersion lens), the red cells are examined for abnormalities in size (macrocytosis, microcytosis) and the degree, if any, of variation in size (anisocytosis) or shape (poikilocytosis), or reduction in the depth of the hemoglobin color (hypochromia), and for variation in color (polychromasia). One must also look for basophilic stippling and the presence of inclusions (eg, nuclei, Howell-Jolly bodies,

Cabot rings, and parasites). The significance of these findings is discussed in Chapter 13.

Next, under 1000X magnification, the numbers of platelets are estimated in several successive fields and compared with their frequency in blood films from normal individuals. One must be certain, from the examination under low power, that clumps of platelets are not present in a few areas, for, if this is the case, a fair appraisal of the platelet count cannot be made by examination of random fields as described. The size (normally, 2 to 5  $\mu$ m) and shape of the platelets are also recorded. The significance of these findings is discussed in Chapters 9, 36, and 37.

After the *leukocyte* count has been estimated by surveying the film under the 100X (low-power) magnification, the differential count is made under about 1000X magnification (Chapter 6). The significance of abnormalities in the leukocytes is discussed in Chapters 42 and 48 to 50.

One must be alert for clues which have bearing on other organ systems, or other aspects of the blood. For example, hypersegmentation of neutrophils may be a clue to anemia caused by deficiency of vitamin B<sub>12</sub> or folic acid (Chapters 6 and 14). Basophilic stippling of red cells may be a clue to neuropathy due to lead poisoning (Chapter 19) or to thalassemia minor (Chapter 27). The obscure cause for severe fever may be solved by the discovery of a microgametocyte in a red cell (Plate XI). Such observations require more care and discernment than does the recognition of the marked lymphocytosis which characterizes chronic lymphocytic leukemia, but they are no less significant to the alert physician and to the patient who depends upon the physician for health care.

### Special Histochemical Stains

The differentiation allowed by any staining reaction is simply a reflection of the differences in chemical composition, reactive acidic or basic groups, and the like, in adjoining structures. The irregular distribution of certain enzymes within any given cell, or among cells of different types, is also used to advan-

tage.<sup>150</sup> The details of these more complex procedures are to be found elsewhere. The principles and main findings are reviewed here. In each case, a "positive" reaction is indicated by the development of a particular color, or the precipitation of granules or other matter specific for the reaction. These localize the substance in question.

### Peroxidase Reaction

This detects an enzyme present in promyelocytes and later cells of the same series and to a lesser degree in monocytes (Plate XX). It is most useful in classifying acute leukemia (Chapter 47), when it may reveal promyelocytes which have too few granules to be visible for certain identification in a smear stained with Wright's reagent. A positive reaction is indicated by blue granules or crystals in the cytoplasm. Lymphocytes and lymphoblasts give a negative peroxidase reaction; myeloblasts have been said to give a negative reaction, but it is a matter of semantics to decide whether leukoblasts which appear to be devoid of granules but which nevertheless give a positive peroxidase reaction should be termed myeloblasts or promyelocytes (Chapter 6).

### Leukocyte Alkaline Phosphatase

This can be quantitated by biochemical procedures on separated, lysed leukocytes (Chapter 6); however, valuable semiquantitative information is obtained by a staining procedure. The enzyme hydrolyzes the substrate naphthol AS-BI phosphate to an aryl naphtholamide which is, in turn, coupled to a soluble diazonium salt, forming an insoluble red azo dye which precipitates at the location of the enzyme.<sup>99</sup> Alkaline phosphatase is present in neutrophilic leukocytes. Increased amounts of activity are found in neutrophilia accompanying infection and in a wide variety of other conditions (page 1279), and in women taking estrogen-progesterone combinations for contraception. Low activity is found in chronic myelocytic leukemia,<sup>102</sup> paroxysmal nocturnal hemoglobinuria,<sup>83</sup> and hypophosphatasia.<sup>4</sup>

### Periodic Acid-Schiff (PAS) Reaction

This detects intracellular glycogen. Megakaryocytes and platelets are richly positive, granulocytes range from a negative reaction in myeloblasts to strongly positive in segmented neutrophils,<sup>90</sup> monocytes often show a few granules, and lymphocytes occasionally show a slight positive reaction. Normal erythroblasts and mature erythrocytes are entirely negative, except in patients with thalassemia (Chapter 26) and those with erythremic myelosis<sup>148</sup> (Chapter 48).

### Sudan Black B

This stain detects lipids. By the improved method of Sheehan and Storey,<sup>158</sup> granules in leukocytes are stained. Leukemic myeloblasts may give a strongly positive reaction, although this is not uniformly so. The reaction is of greatest value in identifying as myeloblasts those cells of a patient with acute leukemia which otherwise appear undifferentiated when examined by Romanowsky stains and which are negative with the peroxidase reaction.<sup>91</sup> Auer rods are strongly sudanophilic.<sup>91</sup> Lymphoblasts, erythroblasts, and lymphocytes give a negative reaction. A positive reaction is found in myelocytes, metamyelocytes, and polymorphonuclear leukocytes of both the eosinophilic and neutrophilic series, most prominently so in the latter.<sup>91,149</sup> Monocytes show minute positive granules, while granules of basophils are variably positive.

### Other Stains

A modification of the Feulgen reaction for deoxyribonucleoprotein is useful in demonstrating nucleoli.<sup>178</sup> The latter will appear as unstained spaces. A methyl-green-pyronin stain affords some measure of the ribonucleoprotein content of leukocytes.<sup>143</sup>

The reticulocyte stain, new methylene blue N, precipitates erythrocyte ribosomes into a network which is visible by light microscopy (Chapter 3).<sup>19,98</sup> It is a most valuable tool for appraising the rate of effective erythropoiesis (Chapters 13 and 20).

The Prussian blue reaction utilizes a fresh, acid solution of potassium ferrocyanide. It detects non-heme iron, ie, *ferritin* and *hemosiderin* iron, in red cells (siderocytes, Chapters 3 and 4), marrow (Chapter 2), and in urine where its detection is of significance in patients with hemolytic transfusion reactions (Chapter 27) or in those with intravascular hemolysis, such as paroxysmal nocturnal hemoglobinuria (Chapter 29) or hemochromatosis (Chapter 4). The same reagent is used to detect hepatic iron excess in hemochromatosis.

Heinz bodies are denatured hemoglobin and have the same tinctorial characteristics as the native protein. They are not visible with Wright's stain. *Crystal violet* will reveal them in a wet preparation as deep purple, irregularly shaped small bodies in the red cells. They may be the result of oxidant drugs (Chapter 23) or unstable hemoglobins (Chapter 24) and may be seen in splenectomized individuals, particularly those with thalassemia (Chapter 26). *Brilliant cresyl blue* will stain reticulum and inclusion bodies, and will precipitate unstable hemoglobins such as Hb Zurich and Hb H.

### Examination of the Wet Film of Blood

Wet preparations are valuable for the demonstration of parasites in blood, some organisms being more easily detected by their pigment (malaria) or by the currents and disturbance they produce in wet films (spirochetes, trypanosomes) than after they have been stained. Wet preparations may be used with or without the addition of sodium metabisulfite for the demonstration of sickling of the red corpuscles (Chapter 25). In fresh, wet preparations the motility of the leukocytes is preserved and their activity and phagocytic power may be studied. Supravital staining is a modification of this technique, dye being added for the purpose of staining the mitochondria and vacuoles (see below). Rouleau formation may be observed; and, after the specimen has stood for 10 or 15 minutes, increase or decrease of fibrin may be roughly gauged.

Fig 1-8. Camera lucida drawings of fresh (human) blood preparations as seen by darkfield illumination. In 1, 2, and 3, adult myeloid granulocytes are shown in various phases of maturation. A, neutrophilic leukocyte; B, eosinophil; C, basophil. In 4, 5, and 6, A and B are myeloblasts; C, D, early myelocytes; E, neutrophilic myelocyte; F, eosinophilic myelocyte; G, basophilic myelocyte; H, lymphoblast; I, J, lymphocytes. K, monocyte; N, normoblast. No. 7 is from a patient having erythroblastic anemia. 8 and 9 from patients infected with *Plasmodium vivax*. In 7, 8, and 9, A is a nucleated red cell; B, erythrocyte containing nuclear chromatin; C, young trophozoites; D, ameboid trophozoites; E, crenated erythrocytes; F, lymphocytes; G, monocyte. Magnification approximately X800. (From Hansen-Pruss<sup>91</sup> courtesy of author and Williams & Wilkins Co.)

A drop of blood from the finger or earlobe is placed on a coverglass. The coverglass is inverted on a glass slide and sealed to the slide with petrolatum or paraffin. The drop of blood should be only slightly larger than a pinhead. If the glassware is clean and the coverglass is deposited gently on the slide,

the blood will spread out evenly under the weight of the coverglass. Pressure should not be applied. The specimen is first examined with the low-power lens of the microscope in order to determine whether it is satisfactory, and then the oil-immersion lens is used. The red corpuscles should lie slightly

separated from one another. Their size, shape, and color may be noted in addition to the other features already discussed. If the microscope condenser is lowered slightly, contrast may be improved and the examination made more easily.

### Darkfield Illumination

Darkfield illumination facilitates the examination of the wet blood film<sup>80</sup> (Fig. 1-8). The leukocytes are exceptionally well seen by this method, for their granules are refractile and set off the nucleus in sharp contrast. Erythrocytes are readily made out because the pericellular membrane is highly refractile. Normoblasts may be distinguished by a faintly perceptible perinuclear membrane. Unstained reticulocytes cannot be distinguished, but, after staining with new methylene blue N or brilliant cresyl blue, the reticulum stands out strikingly. Blood platelets are easily seen because of their refractility and, in addition, numerous small round or dumbbell-shaped particles ("blood dust," hemokonia of Muller) which manifest active brownian movements are found. These may be granules of disrupted leukocytes. Fibrin crystals appear as fine, slightly refractile needles. Malaria plasmodia stand out with clarity, the pigment being highly refractile. Since the parasites remain viable for 10 to 16 hours in these preparations, their growth and development may be observed.

### Supravital Staining<sup>97,114,156,163</sup>

Supravital staining, introduced by Cowdry, was developed and popularized by Simpson and, particularly, by Sabin<sup>153</sup> and her students.

The advantages of supravital staining are: (1) The appearance of the *living, motile cell* is revealed. (2) The method *avoids cell damage* when blood or bone marrow preparations are made.<sup>151</sup> The morphologic types may be readily identified<sup>1,156</sup> and differential counts may be performed reliably. This avoids the problems of interpretation which are espe-

cially prone to occur in leukemia when, in fixed, thin bone marrow smears made in the regeneration phase after chemotherapy or radiotherapy, more than a minor number of cells are damaged in making the smears and cannot be identified after staining.<sup>151</sup> (3) Red cell *inclusions* may be readily seen if appropriate dyes are used; eg, methyl violet reveals Heinz bodies (*vide supra*). (4) *Cell density* and architecture of the aspirated bone marrow spicule are displayed in more nearly their natural state than in thinly spread, pulled, and fixed marrow smears and films.

The disadvantages are: (1) The preparations are not permanent. (2) They must be examined when fresh. (3) They are not suitable for radioautography.

The technique of Forkner,<sup>65</sup> or derivations of it,<sup>38,49</sup> is used. A mixture of neutral red and Janus green in absolute ethanol is flooded onto the surface of a chemically clean slide. Excess dye is drained away and the remaining film on the slide is quickly evaporated by applying heat. In this way a thin, even film of dye is dried onto the slide. The stained side of the slide is marked at once, for it is difficult to identify later.

Pinacyanol (Eastman Kodak Organic Chemicals, Catalog No. 622) has advantages over Janus green as the mitochondrial stain.<sup>156</sup> With rare exceptions, Pinacyanol does not fade out of mitochondria for at least 24 hours, and it stains the nuclear chromatin a purplish blue without interfering with cell viability or motility. It does not impede the staining of vacuoles by neutral red. At a concentration which stains nuclei, Janus green kills the cells. One ml each of 0.4% neutral red and 0.03% Pinacyanol is added to 5.0 ml of absolute ethanol. The freshly prepared mixture is used to make the slides, as above. Since Pinacyanol is light sensitive, the solutions and the slides should be kept in a dark, cool place.

A drop of blood is gently placed on the marked surface of the prepared slide. The preparation is rimmed with petrolatum. The blood may be examined within 15 to 30 minutes; or, if delay is necessary, the preparation may be stored in the refrigerator at a

temperature of about 4° C for as long as 24 hours. A microscope stage, warmed to 37° C, facilitates movement of the leukocytes during study of the blood, but a warmed stage is not essential for identification of the cells.

For successful supravital staining it is necessary (1) to have clean glassware and (2) to avoid the use of so great a concentration of dye that the cells are killed. Death of a cell is indicated by staining of the nucleus with Janus green. A greater quantity of dye must be used for abnormal bloods with a greater than normal number of leukocytes than for normal specimens. In a good preparation the Janus green or Pinacyanol stains the mitochondria a brilliant blue-green, while the neutral red stains the specific granules and vacuoles of the leukocytes in varying shades, depending on their pH: basophilic granules are brick red, neutrophilic granules faint pink, and eosinophilic granules bright yellow. (For detailed descriptions of leukocytes stained "supravitaly," see Chapter 6.)

For the study of bone marrow, lymph nodes, or other tissues where there is an abundance of colorless cells to be stained, more dye is required than for the examination of blood. Imprints may be prepared from a freshly cut, moist surface of tissue. The prepared slide is firmly pressed against the tissue surface for a few moments, without applying any shearing force. Cells will adhere to the slide. If a thin film of intact tissue cannot be obtained, the cut surface is scraped with a sharp scalpel and the tissue accumulating on the knife blade is placed on the slide prepared with the dyes.

### Phase Contrast

Differences of optical path are translated by the phase-contrast microscope into light and shade.<sup>104, 119</sup> Particles which differ in refractive index from the medium in which they are immersed consequently appear brighter or darker than their surroundings. This technique offers greater detail in the study of the finer structure of living, unstained and unaltered cells than is otherwise available. Thus chromatin, mitochondria, the centrosome, and the specific

granules of the cells can be seen clearly, often more distinctly than in stained preparations.<sup>8,9,11,131</sup> Howell-Jolly bodies can be recognized as bright, round bodies inside the erythrocyte; Heinz-Ehrlich bodies as distinct, dark bodies. The various forms of granulocytes can be differentiated by the different appearance of their granulation. Platelets are seen so well that this is the preferred means for their enumeration by hemocytometer technique.<sup>20</sup> The cells of infectious mononucleosis manifest a black and coarse granulation in their cytoplasm which differentiates them from monocytes and ordinary lymphocytes. In certain types of reticulum cells, and especially in myeloma cells, dark drop-shaped formations which have not been found in other cells have been observed adjacent to the nuclear membrane. Distinguishing features have also been described in leukemic and lymphosarcoma cells, lymphoblasts, and myeloblasts,<sup>131</sup> as well as in other types of tumor cells. Auer bodies and nucleoli are particularly well seen.<sup>11</sup> Excellent photomicrographs have been published<sup>1</sup> which convincingly establish the fact that phase contrast is far superior to ordinary bright-field microscopy for the examination of the wet, living blood film.

When microcinematography is combined with phase microscopy, cellular activities which have passed unobserved by ordinary techniques can be seen (Chapter 6, page 224).

### Electron Microscopy

Electron microscopy has made possible the study of cellular detail at the level of 1 nm<sup>12</sup> and has provided extremely valuable information concerning the structure of the cells of the blood<sup>10,73</sup> as well as their function.<sup>11</sup> (See Chapters 3, 6, and 9.) It requires special conditions of fixation, dehydration, embedding, and sectioning.

### Transmission Electron Microscopy (TEM)

A beam of electrons directed in an evacuated chamber through an ultra-thin section of tissue supported on a thin grid is focused by

Fig. 1-9. Ferritin in the cytoplasm of an erythroblast, viewed by transmission electron microscopy. The iron is electron-dense and is seen to be arranged at the corners of a regular octahedron. Insets show two granules displaying a characteristic tetrad structure on thin section. (From Bessis and Breton-Gorius,<sup>13a</sup> courtesy of authors and Henry M. Stratton, Inc.)

electromagnets onto a high-resolution photographic plate. Magnifications up to 100,000X and resolution of point-to-point distances of less than 0.4 nm have been achieved.<sup>87</sup> This is about one thousand times better than resolution with the light microscope. The limita-

tion of resolution for TEM, based upon the wavelength of the electromagnetic radiation, has been calculated to be 0.22 nm.<sup>157</sup> The contrast needed for production of an interpretable image is a function of the ability of the specimen to absorb electrons ("electron

density") and of the atomic number. The greater the latter, the greater the capacity of the atomic nucleus to scatter electrons. As a result, TEM reveals atomic rather than molecular properties of the specimen. For example, it is the iron in the ferritin molecule which enables the identification of the ferritin (Fig. 1-9). Stains which interact differently with different molecules in a specimen to produce contrasting colors for light microscopy are not applicable in electron microscopy. So-called "stains" used in TEM actually deposit atoms of high atomic weight, such as lead, osmium, or uranium, sometimes differentially in reacting with tissues. "Shadowing," by overlaying onto specimens in vacuo, from a point source, a very thin film of platinum, gold, or other heavy metals, yields replicas with imposed contrast which can reveal topological features. When combined with freeze-etching<sup>101</sup> or freeze-cleaving, minute structural details of the erythrocyte membrane<sup>171</sup> and of organelles have been depicted (Fig. 3-11, page 94). Although great detail has been revealed, TEM is limited, as is the high-resolution light microscope, to the two-dimensional image (Fig. 3-3 page 85). Furthermore, TEM requires extremely thin sections. Both factors make it very difficult to gain an impression of the three-dimensional structure of the specimen.

### Scanning Electron Microscopy (SEM)

This provides an image of the surface with perspective which imitates the normal stereoscopic vision, but at the higher magnification and resolution allowed by the electron beam rather than the relatively low resolution and much lower magnification imposed by the longer wavelengths of the visible-light stereoscopic microscope. The SEM moves a beam of electrons as small as 5 nm in diameter across the specimen. The interaction of the beam with the specimen produces secondary irradiation which is generally not focused. Specialized detectors for the several kinds of secondary irradiation provide a signal to

modulate another electron beam which is synchronized with the electron beam in the microscope column and which scans across a standard cathode-ray tube (CRT). The modulation regulates the brightness of the CRT image from point to point and the synchronization of the two beams results in information transfer much as occurs in a television picture tube.<sup>88,89</sup> The magnification is the ratio of the size of the scan in the CRT to that in the microscope column as the electron beam crosses the specimen.

In one mode of operation called cathodoluminescence, visible light is produced in the specimen as the electron beam excites naturally occurring substances in biologic materials or in fluorescent stains or other materials (such as fluorescent antibodies) which have been specifically applied to the specimen. In such arrangements, the detector is a photomultiplier tube and the resultant image localizes the fluorescent materials. The great depth of field and resolution of SEM make this a valuable extension of fluorescence microscopy, at 10,000X magnification!

When the secondary irradiation is in the form of "secondary electrons" rather than visible light, it leaves the surface of the specimen with an intensity which depends upon the angle of incidence of the scanning electron beam. Surfaces of the specimen which are oblique or tangential to the electron beam yield a darker image on the CRT than do those at right angles to the beam. The resulting image creates the illusion of three-dimensional viewing, much as does shading in a skillfully executed drawing or a photograph of an obliquely illuminated object. Extraordinary views of blood cells<sup>13,11,129</sup> (Fig. 3-8, page 92) and bone marrow elements<sup>168</sup> have been obtained with this technique (Fig. 1-10). It conveys a different type of information than does TEM and within a few years since its introduction has become a widely used biomedical research tool.<sup>88,89</sup> The x-ray contrast mode of operation of SEM analyzes the spectrum of x rays produced when the electron beam strikes the target. This provides data on the elemental distribution in the specimen.<sup>88</sup>

Fig 1-10 Normal human sternal bone marrow seen by scanning electron microscopy at an original magnification of 500X. The aspirated specimen was fixed in 6.5% glutaraldehyde and then 1% buffered osmic acid. The adipose cells (A) are in a loose aggregate and are much larger than the normal marrow elements (M) which appear as globules in between them. V denotes a vessel (From Trubowitz et al.<sup>143</sup> courtesy of authors and Henry M. Stratton, Inc.)

# Part II

## The Normal Hematopoietic System

## SECTION 1: *Basic Cytology*

Cells of the blood (erythrocytes, platelets, neutrophils, lymphocytes, monocytes, eosinophils, and basophils) are constantly lost and thus to maintain homeostasis each system must have the capacity for self-renewal. As in all mammalian cell renewal systems, proliferation occurs through cell division. Blood cells other than the lymphocyte and possibly the monocyte differentiate to a point at which cell division cannot or does not occur. Thus, in these systems, renewal involves division of immature cells coupled with differentiation (maturation).

Self-renewal systems must contain *stem cells*. A stem cell can generally be defined as one in which the progeny (daughter cells) of cell division are identical in appearance and potential to the mother cell. A stem cell system which must renew mature nondividing compartments must also be capable of differentiation. Thus, the required characteristics of an hematopoietic stem cell are self-renewal and differentiation.

The production of hematopoietic cells in normal adults is limited to the bone marrow and the widespread lymphatic system. In this section the general principles of cell proliferation and differentiation, stem cell systems, and development of the marrow will be reviewed. The development of the lymphatic system is discussed in Chapter 7.

## Proliferation and Differentiation of Cells

Cellular proliferation and differentiation may occur simultaneously in the same cell or may be independent processes.

### Proliferation

Cells capable of proliferation may be in a generative cycle (G) or in a resting state ( $G_0$ ) from which they can be triggered into G. During the generative cycle the total amount of deoxyribonucleic acid (DNA) doubles and there is an increase in other cellular constituents such as ribonucleic acid (RNA) and proteins. An equal distribution of cellular constituents to each daughter cell occurs during the process of mitosis. Synthesis of DNA appears to be the key to the generative cycle.<sup>13</sup> Synthesis of RNA and other proteins may proceed during  $G_0$  or in cells incapable of proliferation. Synthesis of DNA is limited to cells in G except for unusual circumstances in which the phenomenon of DNA repair occurs, as in cells damaged by such factors as ultraviolet light<sup>16,17</sup> or x-irradiation.<sup>7,18</sup>

### The Generative Cycle

The generative cycle is divided into four phases which may be represented in a circular fashion (Fig. 2-1A) or as a curve (Fig. 2-1B). In the first, or  $G_1$  phase, RNA and protein synthesis begin and at some point in this phase the process triggering DNA synthesis, as yet undefined, is initiated.<sup>15</sup> In the second phase (S), DNA synthesis occurs and is followed by  $G_2$  and in turn by mitosis (M). Protein synthesis and cell volume expansion<sup>19,20</sup> continue throughout the cycle. In general, once DNA synthesis has begun, the generative cycle must be completed or the cell will die. This phenomenon forms the basis for the cell-killing effects of chemicals which inhibit or block synthesis of DNA or block mitosis (Chapter 55).

It appears that there is a real difference between a very long  $G_1$  state and true  $G_0$ . For example, spermatogonial stem cells appear to exist in a state of true  $G_0$ <sup>21</sup> while epithelial cells of the hamster cheek pouch are thought to be in a very long  $G_1$  state.<sup>22</sup> As applied to the treatment of acute leukemia, this distinction is important because a cell in a long  $G_1$  will eventually enter DNA synthesis and be subject to killing by drugs acting

$G_1$  - NUCLEUS CONTAINS DIPLOID DNA

S - PERIOD OF DNA REPLICATION

$G_2$  - NUCLEUS CONTAINS TETRAPLOID DNA

M - PERIOD OF MITOSIS

$G_0$  - RESTING STATE. HAS POTENTIAL FOR DIVISION

GENERATION TIME - TIME FROM ONE MITOSIS TO THE NEXT

Fig. 2-1 the generative cycle (G)

in that phase. On the other hand, a leukemic cell in  $G_0$  would never become sensitive to such drugs unless induced to leave that state.

Deoxyribonucleic acid is the repository of genetic information which is coded in the long polymeric molecule by variation in the sequence of purine and pyrimidine bases. The four bases of normal DNA are two purines, adenine and guanine, and two pyrimidines, thymine and cytosine. A base-deoxyribose-phosphodiester linkage is present; the phosphodiester links the 5' carbon of one deoxyribose unit with the 3' carbon of the next sugar residue.

The synthesis of DNA can be interrupted by a variety of chemical agents (Chapter 55) and the onset of DNA synthesis is selectively blocked by actinomycin D.<sup>15,203</sup> Since actinomycin D is thought to block synthesis of messenger RNA, the trigger for onset of DNA synthesis may be mediated by messenger RNA. However, the effect of actinomycin D in inhibiting DNA synthesis is not noted for more than an hour after drug administration.<sup>15</sup> Consequently, the DNA synthesis trigger may be reasonably remote in the  $G_1$  phase. Inhibiting protein synthesis with drugs such as puromycin delays but does not inhibit the onset of DNA synthesis.<sup>203</sup>

The post-DNA synthesis, premitotic phase ( $G_2$ ) has been well studied with respect to agents which influence subsequent mitosis (see <sup>15</sup>). The rate of protein synthesis decreases during  $G_2$ . Early in  $G_2$  the inhibition of RNA synthesis by actinomycin D leads to failure to enter mitosis, as does protein synthesis inhibition by puromycin in early or mid- $G_2$ . Puromycin administration in the later stages of  $G_2$  allows mitosis to begin but it is not completed. Thus, it would appear that  $G_2$  is a period of preparation for mitosis which includes key RNA and protein synthesis activities. The time of onset of mitosis appears to be more closely related to cell volume than it does to cell age,<sup>17</sup> suggesting that the amount of material synthesized may trigger mitosis.

The duration of  $G_1$  is quite variable and the primary mechanism for shortening the generation time in order to accelerate the rate

of cell production is by shortening  $G_1$ .<sup>34</sup> In rapidly growing mammalian cell systems the duration of S,  $G_2$ , and M is shortened less than  $G_1$ , if shortened at all.<sup>38,195</sup> In plant cells, on the other hand, it is the duration of S which appears to be the primary variable.<sup>213</sup>

Doubling of DNA content during proliferation reflects the reduplication of each of the chromosomes of man. This reduplication is accomplished under the influence of DNA polymerase enzymes by the production of an exact copy in each chromosome of the sequences of guanine, adenine, cytosine, and thymine of each double helix strand of DNA.<sup>15</sup> Except for cells infected with certain RNA viruses<sup>11,202</sup> and in embryonic or leukemic cells<sup>82</sup> or cells in culture, in which RNA-dependent DNA polymerases are found, the DNA polymerase also is DNA-directed. The overall rate of DNA synthesis may be relatively constant throughout the S phase of the generative cycle<sup>226</sup>; however, different chromosomes predictably begin DNA synthesis before others in human marrow cells<sup>197</sup> as well as in other mammalian cell systems.<sup>99</sup> This suggests that an exact regulatory mechanism of DNA synthesis governs the entire S phase.

### Mitosis

The onset of mitosis is signified morphologically by dissolution of the nuclear membrane and organization of the chromatin into individual chromosomes (*prophase*, Fig. 2-2). Chromosomes with their templated duplicates still joined at the reduplicated chromosomal centromere are then aligned (*metaphase*). The tubular mitotic spindles connecting the chromosomal centromere to the cellular centriole contract and one half of each of the duplicated chromosomes is drawn toward each of the centrioles (*anaphase*). A nuclear membrane is formed around each of the two sets of chromosomes, the cytoplasmic membrane invaginates around the nuclei, and the cell separates (*telophase*). In certain normal cells, such as megakaryocytes, and in a variety of diseases, telophase is not completed

Fig. 2-2 The four stages of mitosis. For simplicity of illustration five rather than the normal 46 chromosomes of man are shown in the diagram.

and multinucleated cells are formed. Such cells are said to be polyploid, but differ from cells with an abnormally large number of chromosomes contained within a single nucleus (Chapter 46).

### Chromosome Defects

During metaphase, if cells are caused to swell and break, chromosome spreads can be prepared and stained (Fig. 2-3A). From these the number of chromosomes can be counted

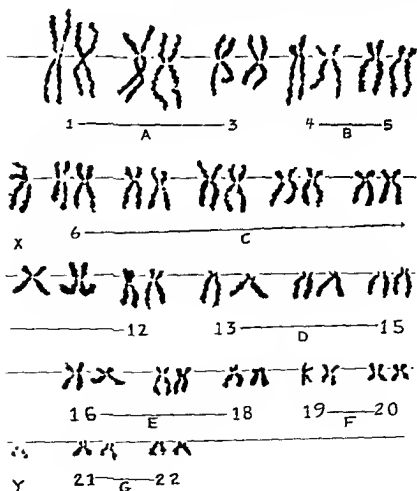

and each chromosome or group of morphologically similar chromosomes can be examined.<sup>117,150,185</sup> The normal number of human chromosomes has been shown to be 46.<sup>72,205</sup> The terminology used in referring to the different normal chromosomes and chromosome groups is presented in Figure 2-3B. Chromosome preparations can be made from any dividing cell system, but are commonly prepared from buccal mucosa or skin cells, blood lymphocytes (induced to divide in culture by the addition of phytohemagglutinin), or bone marrow cells. It is through such examination that chromosome defects associated with a variety of human diseases have been detected.

If a chromosome defect is transmitted by sperm or ovum, or if the defect arises before the first mitotic division of the fertilized ovum, all cells in the body will bear the defect. Chromosome constitution and DNA content generally are constant for all potentially dividing cells in an individual. However, in mature neutrophils a modest loss of DNA may occur.<sup>89</sup> If chromosomes are unevenly divided at the first mitotic division (*abnormal segregation* or *nondysjunction*), theoretically two different defects will be detectable and two different cell lines, one with an extra chromosome and one with a missing chromosome will be present. This circumstance is referred to as *mosaicism*. Mosaicism may also develop later in life when a chromosome abnormality develops in a stem cell line such as the Philadelphia chromosome abnormality of the myeloid stem cell line in patients with chronic myelocytic leukemia (Chapter 48). Two types of cells may also be found if stem cells from a twin or the mother have gained access to the fetus and, because of the fetal immunologic tolerant state, are permitted to grow, a circumstance termed *chimerism*.<sup>51</sup>

Chromosome abnormalities are classed as those of number, in which deviations from the *diploid* number of 46 occur, or those consisting of aberrant forms of individual chromosomes. Disturbances of number may reflect multiples of the normal *haploid* number of 23, in which instance the cell is

Fig 2.3 Normal male karyotype From the photograph of a metaphase spread (A) the chromosomes are arranged in groups according to their size (B) and the paired chromosomes are numbered consecutively, the male chromosome being designated as y and the female as x (Courtesy of Dr. Neil Wald)

*polyploid*. A cell which has lost (*hypodiploid*) or gained (*hyperdiploid*) one or more specific chromosomes so that an abnormal but not polyploid number is present is referred to as *aneuploid*. Aneuploidy is common in patients with acute leukemia, and polyploidy also may occur in these individuals (Chapter 46). The gain or loss of a single chromosome is found in patients with certain congenital syndromes such as the extra 21 chromosome (trisomy 21) in those with Down's syndrome or loss of one of the X chromosomes (monosomy) in those with Turner's syndrome. Abnormalities of chromosome appearance are varied and consist of such changes as an alteration in the position of the centromere from mid (metacentric) toward end (acrocentric) location, constriction of an area, or apparent loss of part of the chromosome. Missing portions of individual chromosomes may be *translocated* onto other chromosomes, rather than lost to the cell.

### Genetic Terminology and Patterns

Detailed consideration of each of the various inherited hematologic disorders will be presented in later sections but a general account of genetic terminology and patterns<sup>137</sup> is presented here.

Genes are the units of inheritance and are sections of DNA strands about which a number of modifying factors affecting phenotypic expression are clustered. They may be *structural* in which case the base sequences dictate protein structure, or *control* genes in which case the base sequences regulate the amount of product. A point mutation produces the structural abnormality of sickle hemoglobin (Chapter 25) and a mutation at a control point may produce thalassemia (Chapter 26). The site of the gene in the DNA strand is termed its *locus* and the corresponding gene on an homologous chromosome is termed its *allele*. Except for the X and Y chromosomes in the male which have no paired chromosomes, all genes have an allele on a paired *autosomal* chromosome.

A congenital disorder may be associated with genetic abnormality (Down's syndrome

with trisomy) and not be *inherited* (neither parent with the abnormality). Proof that the disease is inherited requires demonstration of the genetic defect in an accepted pattern within the family. Certain diseases such as hemophilia (Chapter 37) are inherited, but can also arise by spontaneous mutation. *Familial* defects can be defined as those in which the disorder seems to occur with abnormal frequency in a family but a genetic basis of inheritance has not been proved.

The term *heterozygote* is applied to patients with inherited diseases in whom a gene substitution is present at only one of the two alleles and the term *homozygote* to those in whom the gene is substituted at both alleles. The heterozygote inherits the abnormal gene from only one parent, the homozygote from both. The term *hemizygote* may be applied to a male who has inherited a sex-linked disorder on the X or Y chromosome. The term *double heterozygote* refers to a person who has inherited two phenotypically interacting but separate genetic abnormalities such as when an individual is heterozygous for both hemoglobin S and thalassemia.

Genotype refers to the gene composition of an individual and phenotype to the manner in which genotype is expressed. In a heterozygote there may be no phenotypic expression of an abnormal gene, which is then referred to as a *recessive* gene. A gene having strong phenotypic expression may be called *dominant*. In disease, the terms recessive and dominant are somewhat difficult to apply with any accuracy since by definition their use depends on the degree of sophistication used to study the phenotype. For example, most patients who are heterozygous for the sickle hemoglobin gene are asymptomatic (no superficial phenotypic expression, therefore the gene is recessive); however, if proper laboratory studies are carried out a phenotypic expression can always be detected (therefore the gene is dominant).

The concept of *expressivity* or *penetrance* underlies the use of the terms *recessive* and *dominant*. If the presence of the abnormal gene cannot be detected by any means of phenotypic examination it is said to be *non-penetrant*. Degree of penetrance in an indi-

vidual is modified by the rest of his genetic make-up and by environment.

Equal representation of gene expression for alleles in a pedigree is expected for all autosomal defects. However, defects carried on the sex chromosomes are variably expressed in the two sexes. Defects carried on the X chromosome such as hemophilia (Chapter 37) or primaquine sensitivity (Chapter 23) are expressed in the hemizygous male but will be variably expressed in the heterozygous female. The variable expression of females heterozygous for an X-linked gene may be partly explained by the *Lyon hypothesis*.<sup>124</sup> This suggests that, early in embryogenesis, either the maternally or paternally derived X chromosome in each cell becomes inactive and all descendants of such cells perpetuate that inactivity. This would explain, for instance, why some females heterozygous for hemophilia can be detected phenotypically while others cannot (Chapter 37). However, that such inactivation is not completely uniform is suggested by the observation that heterozygous females with phenotypically detectable hemophilia rarely if ever have defects as severe as their hemizygous sons.

Disease due to sex-linked inheritance involving the Y chromosome has not been detected in man.<sup>137</sup>

### Differentiation

The pattern of differentiation distinguishes one cell line from another since all cells in a normal individual bear the same chromosomal genetic pattern. In general it can be stated that just as DNA synthesis appears to be the key to proliferative activity, ribonucleic acid (RNA) synthesis appears to be the key to differentiation.<sup>42,50,58,87,120,153</sup> At least three classes of RNA molecules are recognized: high molecular-weight ribosomal RNA (rRNA), low molecular-weight transfer RNA (tRNA) with at least one type of molecule for each amino acid, and finally messenger RNA (mRNA). The mRNA molecules transmit the DNA coded message for synthesis of proteins. However, many factors regulate specific processes of differentiation, morphogenesis, and cellular organization.

Detailed knowledge of these is, to date, quite meager.<sup>42,175</sup>

### RNA Synthesis

RNA is transcribed from the DNA template under the influence of DNA-dependent RNA polymerases. The genetic code is followed by transcription of RNA adenine from DNA thymine, RNA uridine from DNA adenine, RNA cytosine from DNA guanine, and RNA guanine from DNA cytosine. Three consecutive base pairs of DNA make up a *codon* and each of the 64 possible codons carries instruction for a specific amino acid or for an instructional message to "start" or "stop" producing a polypeptide chain.

### Protein Synthesis

Protein synthesis is carried out in the cell by interaction of tRNA with mRNA, amino acids, various enzymes, and ribosomes. The *ribosomes*, composed of rRNA and protein, consist of two distinct units, one approximately twice as large as the other, which are joined together by magnesium ions and are the site of polypeptide chain synthesis and assembly. Amino acids are activated by an enzyme specific for each and react with specific tRNA to form amino-acyl-tRNA and then are bound to ribosomes.<sup>40</sup> Single-stranded mRNA moves across a sequence of ribosomes, forming an mRNA-polypeptidyl tRNA complex which is translocated to the polypeptidyl tRNA-binding site on the smaller ribosomal unit. Polypeptide assembly begins at the N terminal end and stops when a triplet coding for "stop" is reached in the mRNA sequence. The specific tRNA is released from the ribosome after its peptide has been added to the chain.

The *nucleolus* is thought to be a primary site of mRNA transcription and to play a significant role in production of ribosomal components.<sup>36,111,112</sup> Nucleolar synthesis appears to be under chromosomal control.<sup>102</sup>

Most ATP-trapped energy required for protein formation as well as that for other cellular events such as mitosis is generated by glycolysis or in the tricarboxylic acid

Fig. 2-4 Interrelation of proliferation and differentiation in the erythron. Erythropoietin triggers a stem cell into erythropoietic activity, perhaps by initiating hemoglobin synthesis. Subsequent maturation through identifiable morphologic stages is accompanied by cell division until midway through the polychromatophilic stage. Three successive cell divisions are illustrated but perhaps as many as six doubling divisions actually occur in the compartment (Chapter 4). During each generative cycle, DNA and RNA per cell double and are then reduced by half at mitosis. Cell volume increases during each cell cycle but does not double, leading to successively smaller cells. Volume contracts further during the process of postmitotic maturation. Cellular DNA, RNA content and volume are step functions in individual cells (solid lines in figure). Since the erythron is not a synchronized population measurement of these values as averages in the population would result in an integral and thus a smooth curve of change (dotted lines in figure). Hemoglobin synthesis persists throughout the mitotic and postmitotic maturation periods but RNA synthesis slows rapidly during the postmitotic period. Synthesis of DNA ceases during the postmitotic phase of the development cycle and most of the DNA is lost from the cell with nuclear extrusion.

cycle, usually in *mitochondria*. The mitochondria also are sites of important enzymatic reactions such as some of those involved in the biosynthesis of heme.<sup>121</sup> It should be noted that energy requirements seem to differ at different stages of the cell cycle. For instance, when energy is not generated, cells fail to enter prophase, but those in prophase complete mitosis.<sup>66</sup> The *Golgi apparatus* is a membrane-bound compartment of the cell containing enzymes involved in adding the more terminal sugar sequences to protein moieties, particularly those of membranes. Lysosomal granules are assembled at this site as are cell surface materials important in various recognition phenomena.<sup>220</sup>

### Interrelation of Differentiation and Proliferation

In certain developing hematopoietic cells, proliferation and maturation proceed concurrently for a period of time. In such systems the daughter cells of mitosis are presumably more mature than the mother cell at the beginning of the generative cycle. Proliferation ceases after a variable number of doubling divisions, but maturation continues. Under normal circumstances, erythrocytes (Chapter 4) and neutrophils (Chapter 6) are virtually mature by the time they enter the blood. However, other cells, such as monocytes (Chapter 6), continue the maturation process after traversing the blood and entering such tissues as the spleen, peritoneal cavity, and lung. An example of the interrelation of proliferation and maturation as it is seen in the erythroid compartment is shown in Figure 2-4.

## Hematopoietic Stem Cells

### Stem Cell Systems

As noted in the introduction to this section, each of the blood cells must be replenished from a stem cell compartment which remains stable in size under homeostatic conditions. In a stem cell compartment which remains stable in size but supplies differentiated cells, a cell must be added to the compartment by proliferation within the compartment for

each cell which leaves by the process of differentiation.<sup>171,221</sup> Osgood<sup>155</sup> suggested that such compartments are maintained by each cell division, resulting in one cell which leaves by differentiation and one which remains in the compartment (Fig. 2-5A), an asymmetric form of cell division. He termed

Fig 2-5 Models of stem cell replication. As discussed in the text, it has been suggested that division in stem cell compartments may be asymmetric (A) or symmetric (B). Compartment size is maintained in A by differentiating stimuli triggering cellular division in which one daughter matures and the other remains a stem cell. In B the differentiating stimulus depletes the compartment by inducing cellular differentiation, but a secondary "compartment depletion recognition loop" induces stem cell division to maintain compartment size.

this  $\alpha$ -N division and thought  $\alpha$ -2 $\alpha$  division in which both daughters remain stem cells to be an unusual event. An alternate model<sup>113,221</sup> separates the processes of differentiation and cell division and avoids the concept of asymmetric cell division. In such a model (Fig. 2-5B), for each cell which is triggered into differentiation and thus leaves the stem cell compartment, another is triggered into  $\alpha$ -2 $\alpha$  type division, thus maintaining a stable compartment size.

The exact structure and interrelationships of hematopoietic stem cell compartments are not known. On the basis of morphologic observations,<sup>111</sup> Maximow<sup>114</sup> and others considered it probable that all blood cells are derived from a common stem cell—the *monophyletic* theory. Others, such as Sabin and co-workers,<sup>184</sup> suggested that there is a separate and distinct stem cell compartment for each of the blood cells—the complete *polyphyletic* theory. Still other theories intermediate between these extremes (dualist, trialist, neo-unitarian, etc) were proposed by Naegeli, Schilling, Downey, and others (see Downey<sup>65</sup> and earlier editions of this book for a more complete discussion). Current evidence suggests that both the mono- and the polyphyleticists were correct.

Presently available data directly relating to stem cell compartments are derived mainly from studies of hematopoietic spleen colonies in the mouse,<sup>21-200</sup> colonies of granulocytic cells grown in vitro from marrow and blood of the mouse<sup>31</sup> and man,<sup>41,169</sup> or grown in vivo in diffusion chambers,<sup>30</sup> and from chromosomal or other cell changes associated with human diseases.<sup>185</sup>

Till and McCulloch<sup>209</sup> demonstrated a linear relationship between the number of marrow cells injected into lethally irradiated mice and the number of macroscopic nodules of hematopoietic tissue present on the surface of the recipient's spleen 10 days following the injection. Subsequent cytogenetic studies<sup>16,151</sup> disclosed that these colonies were *clonal*; i.e., they had arisen from a single cell. Such colonies may contain erythrocytes, neutrophils, megakaryocytes, and eosinophils, indicating that the colony-forming unit

cell (CFU cell) is pluripotent for the erythroid, neutrophilic, eosinophilic, and megakaryocytic cell lines. Cytogenetic data from patients with chronic myelocytic leukemia (CML) are compatible with the existence of such a cell in man.<sup>185</sup> When the Philadelphia chromosome abnormality (Chapter 46) is present in such patients it is demonstrable in precursors of erythrocytes, neutrophils, and eosinophils and probably in megakaryocytes but not in lymphocytes or buccal mucosa cells. It may also be present in marrow fibroblasts,<sup>126</sup> raising questions concerning a common fibroblast-hematopoietic stem cell. This suggests that CML is clonal in nature, beginning in a single cell which is pluripotent for the above four cell lines but not for lymphocytes. Other evidence supports the clonal nature of CML (Chapter 46). Similarly, in persons with paroxysmal nocturnal hemoglobinuria (Chapter 29) a membrane defect is present in erythrocytes, neutrophils, and platelets, thus suggesting a common origin for these cell lines.<sup>9</sup>

None of these studies throws light on the question of a common or separate origin of monocytes and basophils from neutrophils, eosinophils, or other cells. However, colonies grown in semisolid media from human marrow<sup>169</sup> or human blood<sup>44</sup> contain neutrophils, eosinophils, and monocytes. Since these colonies are clonal in nature, at least in man,<sup>46</sup> these observations in addition to the myeloblast-monoblast mixtures observed in patients with acute leukemia (Chapter 47) suggest a common origin for neutrophils, eosinophils, and monocytes.

In none of the above studies is there any suggestion that lymphocytes share a common precursor with other blood cells. Yet, under conditions of extreme cellular deprivation in the mouse, there is cytogenetic evidence that such a cell exists. In mice which recover from extreme depression of stem cell pools, a similar chromosome aberration was observed in hematopoietic spleen colonies and in lymphoid tissues.<sup>151,224</sup> The immune system of lethally irradiated mice has been repopulated with cells from spleen colonies.<sup>210</sup> In man, associated lymphocytic and erythrocytic de-

fects may be observed<sup>74</sup> and coexistence of congenital defects marked by marrow hypoplasia and hypogammaglobulinemia<sup>141</sup> are consistent with the concept of a cell pluripotent for myeloid and lymphoid tissue.

Lymphocytes appear to form a stem cell compartment under steady-state conditions. Small lymphocytes are capable of "blastic" transformation, cell division, and presumably reversion to small lymphocytes (Chapter 7).

The CFU cell appears to be in a state of  $G_0$  since high doses of tritiated thymidine or hydroxyurea (agents which kill cells in DNA synthesis, Chapter 55) do not kill an appreciable number of CFU cells when given to normal mice.<sup>35,176</sup> If the CFU compartment is not proliferating to any appreciable degree, it must be assumed that, under normal conditions, blood cell production is maintained from more mature stem cell compartments. Evidence for a more mature granulocyte and erythrocyte stem cell compartment has been presented. For example, the  $WW^v$  mouse has a genetic defect in CFU cells such that its marrow cells fail to produce macroscopic colonies in irradiated recipients. Yet, its marrow cells produce a normal number of normal-sized *in vitro* granulocytic colonies in soft agar.<sup>18</sup> Similarly, the size of the most mature stem cell system for erythrocytes, the "erythropoietin-sensitive cell" compartment, fails to parallel measured changes in the size of the CFU cell compartment, suggesting that these are separate cellular compartments.<sup>110,146,154</sup> Separation of cells from marrow or other tissues by various techniques tends to concentrate CFU cells, *in vitro* granulocytic colony-forming cells, and erythropoietin-sensitive cells into different fractions.<sup>93,143</sup>

In summary, present evidence favors a model for stem cell compartments (Fig. 2-6) with the following characteristics.

1. Differentiated stem cell compartments replenish blood cells under ordinary conditions. Neutrophils, eosinophils, and monocytes normally share a common compartment as judged by their coexistence in *in vitro* colonies.<sup>169</sup>

2. If the differentiated compartments are

damaged<sup>435,176</sup> or if an increased demand for mature cells is imposed,<sup>25</sup> a compartment normally in  $G_0$  begins proliferation and differentiation to replenish stem cell compartments for erythrocytes, megakaryocytes, neutrophils, eosinophils, and monocytes.

3. With extreme hematopoietic damage, a cell which is pluripotential for all blood cells is activated in order to replenish other stem cell systems.<sup>151,224</sup>

It is possible that these separate compartments are really a single compartment. Most studies which indicate their separateness rely upon demonstrating a difference in the proportion of cells in a generative cycle. An alternative explanation would be that there are differences in response to differentiation and differences in transplantability in association with changes in the cell cycle in a single stem cell compartment.

As yet, pluripotential stem cells cannot be identified. The small lymphocyte has been the prime candidate for the pluripotential cell since the time of Maximow<sup>134</sup> and, among others, Yoffey and co-workers<sup>143</sup> have favored the intermediate-sized lymphocyte (the transitional cell). Hematopoietic spleen colonies do not arise from transplanted lymph node, thymus, or thoracic duct lymphocytes, but can be obtained by transplanting cells from the marrow, spleen, blood, or peritoneal cavity.<sup>24</sup> Cells (presumably lymphocytes) responsible for graft-versus-host disease are separable from hematopoietic stem cells by sedimentation.<sup>168</sup> This indicates that the usual peripheral lymphocyte is an unlikely candidate for the pluripotential cell. However, cells with the morphologic appearance of lymphocytes are present in all of the above sources of colony-forming cells and thus the possibility of a "specialized" lymphocyte cannot be ruled out. Certain fractionation studies of marrow suggest that fractions concentrating lymphocytes also concentrate colony-forming cells.<sup>54</sup> However, gradient centrifugation also concentrates colony-forming cells in certain fractions which differ from the fractions containing small lymphocytes.<sup>93,143</sup> Colony-forming cells have been found in inflammatory exudates, and this and

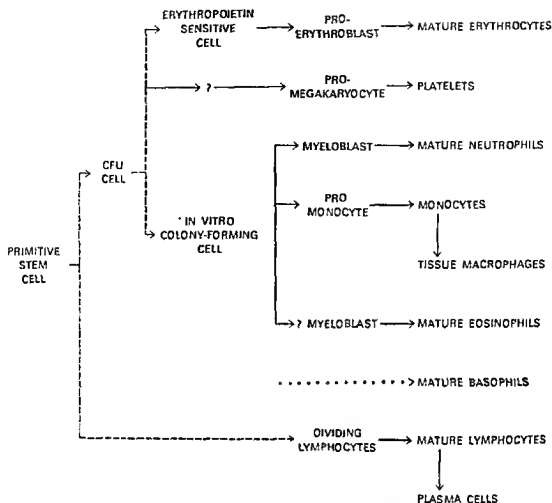

Fig 2.6 Interrelationship of blood cell origin. This diagram represents a possible structure of stem and mature cell compartments based on current evidence (see text). The most immature cell ("primitive" stem cell) is pluripotent for all blood cells. One of its progeny, the cell which forms spleen colonies in the mouse ("CFU" cell), is in turn pluripotent for all cells except the lymphocyte. Still more differentiated stem cells, such as the erythropoietin-sensitive cell, regularly maintain mature cell compartments. Solid lines represent pathways of regularly occurring cell flow in normal animals. Dashed lines represent pathways followed under circumstances of stress. The dotted line indicates the absence of data on basophil origin.

some ancillary evidence have been interpreted as favoring the monocyte as a colony-forming cell.<sup>13</sup>

The possible identity of the more differentiated stem cells will be considered in the chapters dealing with differentiation patterns of specific blood cells (pp. 181, 238, 298, 380).

### Regulation of Stem Cell Production

In general it can be stated that hematopoiesis is maintained in a steady state in which production of mature cells equals

cell loss. Increased demands for cells as a consequence of disease or physiologic change are met by increased cell production. Thus, the system must be subject to some form of feedback control. Such control could be exerted by humoral factors or on the basis of local cell concentration through cell-cell interaction.<sup>171</sup> There is evidence which suggests separate and distinct humoral control systems of erythrocytic (Chapter 4), neutrophilic (Chapter 6), and megakaryocytic (Chapter 9) tissue, but as yet no direct evidence of control of the hematopoietic system by cell-cell interaction has been presented.

Control of the size of the CFU compartment is even less well understood than are control mechanisms in differentiated cell compartments. The observation that irradiation of one limb leads to generalized proliferation of the compartment suggests humoral control.<sup>76</sup> However, attempts to demonstrate a CFU growth-promoting factor in mouse plasma have been unsuccessful to date.<sup>28</sup> If the entire CFU compartment is reduced in size, as by giving whole-body irradiation, self-replicative regrowth begins almost immediately.<sup>45</sup> Stimulation of mature cell production, as by injecting erythropoietin,<sup>131</sup> bleeding, or by injecting endotoxin,<sup>27</sup> leads to a prompt expansion of the CFU compartment. Thus, CFU cell proliferation is enhanced by reduction of compartment size or by increasing the demand for mature cells.

Differentiation, in the absence of self-replication,<sup>207</sup> is potentially suicidal for a stem cell compartment, particularly if the compartment has been reduced in size. An efficient protective mechanism may exist for the CFU compartment. After the compartment has been reduced to less than 10% of normal by irradiation, no differentiation can

be detected until regrowth by self-replication has partially restored the compartment.<sup>45</sup> The pathway of differentiation of CFU cells is geared to the degree of demand for such cells. Once differentiation begins in a reduced CFU compartment the relative output into erythroid or granulocytic lines is governed by the respective degrees of demand for each cell type.<sup>43,97</sup>

## Blood Formation in the Embryo and Fetus

Hemoglobin synthesis is initiated in the yolk sac in all embryonic vertebrates during the mesoblastic period of hematopoiesis.<sup>22,65</sup> Most investigators favor a mesenchymal rather than an entodermal origin for the blood islands of the yolk sac.<sup>98,204</sup> These cells produce unique hemoglobins (Fig. 2-7) not found during later erythropoiesis in any species yet studied<sup>14</sup> (see Chapter 4 for detailed discussion of hemoglobin types and structure).

The globin of the first detectable hemoglobin in the human embryo consists of

Fig 2-7. Proportions of the various human hemoglobin polypeptide chains through early life. The hemoglobin electrophoretic pattern (Gower-2, Gower-1, Hb-F, Hb-A, Hb-A<sub>2</sub>) typical for each period also is shown (From Pearson,<sup>163</sup> courtesy of author and C. V. Mosby Co)

polypeptide chains which differ from all other hitherto recognized globin chains and have been designated epsilon chains (Gower type I hemoglobin,  $\epsilon_1$ )<sup>96,100</sup> Shortly thereafter, production of normal alpha chains of hemoglobin begins and the yolk sac hemoglobin then can be represented as  $\alpha_2\epsilon_2$  (Gower type II hemoglobin) (Fig. 2-7) Insofar as has been determined, all circulating erythrocytes produced at this stage are large nucleated erythrocytes with immature-appearing nuclear chromatin. These cells are similar to and were regarded by Ehrlich, probably erroneously, as identical to the megaloblasts of pernicious anemia (Chapter 14) Demonstration of the unique hemoglobin in the yolk sac has led to the suggestion that these erythrocytes may be from a different cell clone than are later erythroblasts.<sup>109</sup> However, cells from the mouse yolk sac produce adult hemoglobin in culture.<sup>12</sup> Moore and Metcalf<sup>114</sup> demonstrated that migration of yolk sac stem cells was responsible for all subsequent hematopoietic development in the mouse. Thus, it appears that the unique  $\epsilon$  chains are formed in response to environment rather than being derived from a unique hematopoietic cell.

Beginning at approximately the sixth week of embryonic life, yolk sac production of erythrocytes decreases and production of erythrocytes within the human embryo begins. By approximately ten weeks, yolk sac erythropoiesis is undetectable.<sup>22,98</sup> Erythropoiesis is detectable in fetal liver by approximately six weeks, in fetal spleen by approximately 12 weeks, and in marrow by approximately 20 weeks.<sup>108</sup> By the time of full gestation, virtually all erythropoiesis is confined to the marrow.

Throughout fetal life, erythroblasts of liver, spleen, and marrow primarily produce fetal (F) hemoglobin ( $\alpha_2\gamma_2$ ) (see Chapter 4). It is not until after birth that appreciable conversion to adult hemoglobin is noted. In addition to Hb-F, cord blood contains two minor components (10%) designated  $F_1$  and  $F_{11}$ .<sup>4,150</sup> Nephrectomy and starvation fail to decrease neonatal hematopoiesis in rats,<sup>122</sup> but hypertransfusion results in suppres-

sion.<sup>225</sup> Hepatic erythropoiesis is stimulated by erythropoietin during certain stages but not during others.<sup>48,179</sup> These studies suggest that fetal hematopoiesis may proceed independently of erythropoietin or that erythropoiesis proceeds maximally at certain stages and cannot be further augmented. Production of fetal as well as adult hemoglobin was stimulated by erythropoietin in *in vitro* cultures of the marrow of newborn calves,<sup>78</sup> but no stimulation of fetal hemoglobin was demonstrable in similar culture of marrow of newborn human infants.<sup>149</sup>

Erythrocytes derived from yolk sacs are large (1800 to 2400  $\mu$ <sup>108</sup>) nucleated primitive cells<sup>22,134</sup> and have a shorter life span than adult erythrocytes, virtually all of them having disappeared by the fourth month. Later in fetal erythropoiesis, erythrocytes are smaller than yolk sac cells, but they still are macrocytic by adult standards. They generally lose their nucleus before entering the circulation.<sup>222</sup> Circulating red cells reach one million/ $\mu$ l between the second and third fetal month and then increase steadily to approach normal adult levels shortly before the end of normal gestation (Fig. 2-8).

Granulocyte precursors and megakaryocytes are demonstrable during later stages of yolk sac hematopoiesis, at least in some species.<sup>108,134,170</sup> (Fig. 2-9), but probably not in man.<sup>98</sup> Lymphocytes are not discernible (Chapter 7). Granulocytes and megakaryocytes are present during hepatic and splenic phases of hematopoiesis and megakaryocytes can be found in the circulation by 12 weeks.<sup>148</sup> However, it is not until hematopoiesis begins in marrow that granulocyte and megakaryocyte production becomes prominent. There is evidence in the mouse that the environment of the spleen is more favorable for erythrocyte than granulocyte production, as compared to the marrow.<sup>223</sup> Granulocytic stem cells are abundant in fetal mouse liver, but few granulocytes are formed there.<sup>178</sup> These data suggest that the marrow is the only potentially hematopoietic organ with the proper environment for full development of granulocytic and megakaryocytic tissue.

Fig. 2-8. The red corpuscles of human fetuses of different ages compared with those of the newborn and adult. Erythrocyte counts are represented by solid circles, mean corpuscular volumes by squares, mean erythrocyte diameters (measured in wet preparations) by crosses, proportion of nucleated red corpuscles by black triangles, and proportion of reticulocytes by open circles (From Wintrobe and Shumacker,<sup>222</sup> courtesy of the authors and American Society of Clinical Investigation, Inc.)

Fig. 2-9. Stages of hematopoiesis in the embryo and fetus, indicating the comparative participation of the chief centers of hematopoiesis and the approximate times at which the different types of cells make their appearance

## Blood of Newborn Infants and Children

The normal values for certain blood cells differ in infants and children compared to adults. Mauer<sup>133</sup> and Oski and Naiman<sup>161</sup> have reviewed these changes in greater detail than will be done here.

### Erythrocytes

The hematocrit of cord blood of full-term infants averages 52% (95% limits 47 to 57)<sup>55</sup> and there is little if any correlation between level of cord blood hemoglobin and birth weight or infant maturity.<sup>41</sup> In the few hours following birth the hemoglobin concentration in venous blood samples increases approximately 10%<sup>50, 51</sup> as does the hematocrit.<sup>62, 114</sup> This increase is probably due to infusion of cord and placental blood with subsequent reduction of plasma volume, as it is not observed if special attempts are made to clamp the cord early.<sup>62, 114</sup> Approximately

50 ml of placental blood are transferred to the newborn within the first minute after birth.<sup>211</sup>

At birth, as many as 24 nucleated erythrocytes per 100 leukocytes may be present in apparently normal infants, but these disappear by approximately four days.<sup>7</sup> As many as 5% reticulocytes are present at birth<sup>216</sup> and erythrocytes are quite macrocytic with an average mean corpuscular volume of 113 fl.<sup>68</sup> The life span of the red cells of the newborn is approximately three fourths that of the adult.<sup>83, 164</sup>

Erythrocyte production slows immediately after birth (page 69). By four days the hematocrit begins to decrease and continues to decline during at least the first two months of life and perhaps for longer periods.<sup>131, 149, 152</sup> The reduced erythrocyte production probably reflects two factors, both of which would result in decreased erythropoietin production (Chapter 4), namely, increased oxygenation of blood through the pulmonary as compared to the placental route and the increase in hematocrit produced by

Fig 2-10. Normal curve for hemoglobin, red cells, and volumes of packed red cells from birth to old age. The mean values are heavily outlined. The range of variation is indicated by dotted lines for hemoglobin, interrupted lines for red cell count and dotted interrupted lines for volume of packed red cells. The scales for hemoglobin, red cell count and volume of packed red cells are similar and therefore the relative changes in these three values are apparent on inspection. The scale for age, however, is progressively altered.

infusion of cord and placental blood. Erythropoietin can be detected in the plasma of the newborn and then is undetectable for two to three months.<sup>129</sup> This does not reflect inability to produce erythropoietin since it is increased in the plasma of anemic or hypoxic infants.<sup>90</sup> Evidence for an inhibitor of erythropoiesis in neonatal plasma has been presented.<sup>196</sup> Additional factors contributing to the decline in hematocrit observed after birth are hemolysis and an expanding plasma volume.<sup>152</sup> The "physiologic anemia" of newborns may be more severe in premature infants than in full-term infants. In prematures, "normal" hemoglobin levels have been reported to be as low as 6 g/100 ml at the age of three to seven weeks.<sup>152</sup> In full-term infants, minimal hemoglobin values are approximately 9 g/100 ml at the age of seven to nine weeks.<sup>132</sup>

Exact normal values for erythrocytes in infancy and childhood are difficult to establish<sup>77</sup> owing to the frequency of iron deficiency in infants (Chapter 17). However, following the postnatal decline, average values remain below those of adults until teenage is reached (Fig. 2-10). The macrocytosis present at birth disappears by three months.<sup>61,132</sup> Between the ages of five months and three years, minimal normal values of 10.5 g per 100 ml hemoglobin and 34% hematocrit seem reasonable.<sup>86,91,132,133</sup> Total blood volume correlates reasonably well with linear height of children.<sup>52</sup> By puberty, values for boys and girls are equal to or perhaps exceed those found in adult women.<sup>81,133</sup> In 471 healthy children living near sea level, aged 11, 12, or 13, we found mean VPRC as determined in the Wintrobe hematocrit to be 44 ml/100 ml (95% confidence limits 41 to 49) and values in boys and girls were identical.

### Blood Leukocytes

*Neutrophil concentration* (Fig. 2-11) is quite high at birth and may rise even higher during the first days of life. At birth there is a moderate shift to the left; metamyelocytes are easily found and myelocytes and even

promyelocytes may be observed.<sup>106</sup> Within two weeks, neutrophil concentration declines to within, and occasionally below, normal adult levels. The neutrophil concentration in children four years of age or older is the same as in adults.<sup>157-160</sup> *Lymphocyte concentration* is high at birth and rises to values as high as 22,000 in some apparently healthy infants during the first year of life.<sup>215</sup> A gradual decline is observed throughout childhood, but even teenagers have higher concentrations than adults.<sup>157-160</sup> *Eosinophil concentration* may be rather high during the first year of life and tends to be higher in children than in teenagers or adults. *Monocyte* levels are high during the first year but thereafter are at adult levels. No significant relation of age to *basophil* concentration has been detected.

### Platelets

The platelet count of normal, full-term infants is similar to levels in adults.<sup>1</sup> There is disagreement in the literature as to whether otherwise normal premature infants commonly<sup>139</sup> or uncommonly<sup>71,105,165</sup> are thrombocytopenic. Platelet counts appear to be maintained at normal adult levels throughout infancy and childhood.

## Extramedullary Hematopoiesis

Formation of apparently normal blood cells outside the confines of marrow has been noted in post-fetal life under a variety of circumstances (Chapter 57). The spleen is the most commonly encountered site, but hematopoiesis in liver, lymph nodes, and, less commonly, adrenal glands, cartilage, broad ligament, thrombi, adipose tissue,<sup>75</sup> intrathoracic areas,<sup>49</sup> kidney, and endostium<sup>32</sup> also has been recorded. These hematopoietic islands may be composed of apparently pure or mixed erythrocytic, granulocytic, or megakaryocytic tissue, reminiscent of the clonal spleen colonies of the mouse recovering from irradiation (page 50).

Fig. 2-11. Values for blood concentration of neutrophils and lymphocytes (above), and of monocytes, eosinophils and basophils (below) during infancy and childhood (Compiled from the data of Kato<sup>106</sup> and Washburn<sup>215</sup> for infants and from data of Osgood and co-workers<sup>137 138 139 160</sup> for older children)

In general, extramedullary hematopoiesis has been found in association with diseases characterized by increased production of one or more types of cell (erythroblastosis fetalis,<sup>32</sup> pernicious anemia,<sup>123,140</sup> thalassemia,<sup>198</sup> sickle cell anemia,<sup>191</sup> hereditary spherocytosis,<sup>49</sup> and various leukemias<sup>104,186</sup>). Chronic bleeding or chronic poisoning of cell production will produce extramedullary hematopoiesis in animals.<sup>83</sup> However, increased demand for cells in the face of decreased production does not necessarily lead to extramedullary cell production. Aplastic anemia is rarely associated with extramedullary hematopoiesis.

In most of the above instances, abnormally immature cells are found in the blood. As is discussed on page 60, cell release even from normal marrow is not understood. It is possible that the factors inhibiting the release of immature cells from normal marrow are not operative at extramedullary sites.

## Medullary Hematopoiesis

In normal adults, marrow which is active in hematopoiesis is limited to the vertebrae, ribs, sternum, pelvis, scapulae, skull, and extreme proximal portions of the humeri and femora. The marrow cavity of the remaining bones of the limbs is filled with fat. Under abnormal conditions characterized by long-standing increased hematopoiesis, a peripheral expansion of active hematopoietic marrow may be observed.<sup>130</sup> In infants and children, active hematopoiesis takes place in more distal portions of the extremities than in adults. Crude estimates of the location of active hematopoietic marrow can be obtained by injecting appropriate isotopes and scanning the entire body for radioactive emissions.<sup>3,212</sup> Labeled colloids are phagocytosed by the reticuloendothelial cells of the marrow and in the normal state their distribution is equal to the distribution of active hematopoiesis. However, in the presence of disease the extent of active marrow estimated by means of labeled colloids may differ from that estimated by radioactive iron.<sup>212</sup>

## Anatomy of the Bone Marrow

The marrow cavity of the bones of man is partially compartmentalized by plates of bone trabeculae protruding into the cavity at right angles to the external medullary bone. Hematopoietic marrow contained within this space is a loosely knit gelatinous to semifluid tissue rich in fat.

The vascular system of the marrow is complex and hematopoietic cell production appears to follow the vascular arrangement rather exactly.<sup>59,219</sup> Centrally located nutrient arteries coursing through the marrow cavities send out branches which terminate in capillary beds within the bone or, less frequently, at the periphery of the marrow space. Certain of the capillaries or post-capillary venules (vessels of the osteal canals) reenter the marrow cavity and coalesce to form large, venous sinuses in which the somewhat sluggish flow is again toward the center of the cavity. These sinuses often have a complex pattern of intercommunication, but eventually flow into the central vein, which follows the same general course as the central artery. Hematopoietically active parenchyma and fat fill the space between the sinusoids. Light and electron microscopy indicate that hematopoiesis takes place outside,<sup>59,219</sup> rather than within,<sup>153</sup> marrow sinusoids. Blood flow to marrow is rapid, calculated as 0.5 ml/g of marrow tissue/min in rabbit femurs.<sup>55</sup>

The wall of the venous sinusoids of the marrow is primarily composed of a unicellular endothelial cell network.<sup>60,219</sup> In other sinuses, such as those of the spleen (Chapter 8), two additional components of sinusoidal walls are regularly present, a basement membrane and an adventitial cell layer. In marrow sinuses, these components are intermittently found but they are so discontinuous that the endothelial layer constitutes the only continuous component. When a basement membrane is found it is usually at a location where a muscular artery lies close to the endothelial layer.<sup>60</sup> Fenestrations and areas of discontinuity of the endothelial lining have been reported.<sup>219</sup> However, others<sup>354,60</sup> have described the membrane as being continuous

fenestrations occurring in the endothelial cell itself only when that cell is penetrated by an emerging blood cell. Whether fenestrations normally exist or only develop with trans-endothelial passage of blood cells is an important question with respect to the mechanisms of release of cells from marrow (see below). Adventitial cells extend into the hematopoietically active sections with their cytoplasmic membrane fitting in between and conforming to the contour of hematopoietic cells. The "proteinaceous" material noted between hematopoietic cells in light microscopy is adventitial, or endothelial, cell cytoplasm according to some electron microscopy studies.<sup>219</sup> *Adventitial cells are classed as reticular cells* (Chapter 8), that is, they are considered to possess the capacity to form reticular fibers and to be phagocytic. As a rule, little phagocytic activity is noted in endothelial cells. The proposal that these cells may serve as stem cells for hematopoiesis<sup>134</sup> has received no substantiation. However, when parenchymatous marrow is mechanically removed from the bone of an animal, regeneration may be from residual local stem cells in the bone rather than from circulating cells<sup>125</sup>; a similar pattern has been reported in studies of extramedullary marrow implants.<sup>128</sup> The type of cell leading to this regeneration is unknown, but there is evidence that osteoblasts and hematopoietic cells arise from separate stem cells.<sup>6</sup> The fat cells of marrow primarily represent accumulation of fat within adventitial cells, although endothelial cells may also accumulate fat.

Hematopoiesis occurs within the parenchyma of marrow, bounded by the sinusoids. In both light and electron microscopy, specific types of cells in various stages of development tend to aggregate. That is, the impression is gained that a small island of pure erythropoiesis abuts a similar neutrophil island and that cells are not scattered at random.

#### Release of Cells from the Bone Marrow

The control of cell release and the exact mechanisms of release are incompletely un-

derstood. There seems no doubt that cells leave the parenchyma and enter the sinusoids through fenestrations of the endothelial cells lining the sinuses, but how these fenestrations are created is not clear. As already noted, there is disagreement as to whether endothelial fenestrations normally exist in the absence of migrating blood cells.

Since granulocytes are motile and become more motile and more deformable<sup>119</sup> as they mature, it has been assumed that they migrate directionally toward the sinusoid. One hypothesis to explain the action of neutrophil-releasing factor<sup>26</sup> would be to suggest that this factor acts as an attractant for mature neutrophils.

Megakaryocytes usually are observed in close proximity to the sinusoidal membrane, and cytoplasmic processes fenestrating endothelial cells have been described.<sup>60,219</sup> Thus, direct release of platelets into the sinusoid through cell rupture or theoretically through shedding of cytoplasm requires only disruption of the megakaryocyte cytoplasmic membrane (Chapter 9).

The mechanism underlying release of the basically nonmotile erythrocyte is unknown. In response to acute hemorrhage, a sudden increase in the number of mature erythrocytes in marrow parenchyma is observed.<sup>219</sup> This suggests that certain vessels may empty directly into the parenchyma and under certain circumstances may "wash" cells from the parenchyma into the sinuses. Sinusoidal dilatation with attendant increased blood flow accompanies hypoxia.<sup>57</sup> Adventitial cells can shift position in response to enlarging sinuses, perhaps compressing the parenchyma and "squeezing" out cells by contracting the parenchymal space.<sup>219</sup> The viscosity of "intercellular" materials of marrow parenchyma has been suggested as a means of influencing erythrocyte release. Induction of erythroid hyperplasia in rabbit marrow led to decreased viscosity; granulocytic hyperplasia caused increased viscosity.<sup>39</sup> However, as noted earlier, what appears to be "intercellular" material by light microscopy has been suggested to be adventitial cytoplasm by electron microscopy.

One important factor in cell release appears

to be cell deformability. Reticulocytes and mature red cells<sup>217</sup> and granulocytes<sup>119</sup> are much more deformable than are their precursors. Perhaps release is controlled by a combination of changing blood flow directly into parenchyma, sinusoid and parenchymal volume, and levels of cell attractants in sinusoidal blood. Whether a cell is actually released may depend upon its ability to deform enough to traverse the fenestrations of the sinusoidal wall.

Accelerated platelet or neutrophil release can occur as isolated phenomena. Accelerated release of red cells usually is accompanied by accelerated release of other elements. For instance, following acute hemorrhage or with a brisk hemolytic anemia, the early release of reticulocytes usually is accompanied by accelerated neutrophil and platelet release (Chapter 4). However, with accelerated platelet release in certain thrombocytopenias (Chapter 34) or accelerated neutrophil release (Chapter 6), accelerated release of other cells usually is not seen. These observations can be interpreted as suggesting specific humoral releasing factors for platelets and neutrophils.<sup>28</sup> Red cell release, on the other hand, appears to depend more on mechanical factors.

Diseases of marrow structure such as myelofibrosis or carcinomatous invasion (Chapter 57) could disrupt areas of sinusoidal architecture. In leukemia and related diseases (Part V, Section 3) the expanded parenchyma itself may possibly change the size of sinusoidal fenestrations. Certainly, in most circumstances in which immature cells are found in the blood, there is evidence for some change in marrow structure or there is extramedullary hematopoiesis.

#### Number of Hematopoietic Cells in Bone Marrow

Estimates of the total number of hematopoietic cells within the marrow cavities of man have been made by a variety of techniques. The rate of plasma iron turnover (Chapter 4) bears a direct relation to the total number of nucleated erythrocyte precursors in the marrow of normal man as well as in

patients with various diseases.<sup>70a</sup> The derived value is approximately  $3.5 \times 10^9$  normoblasts/kg in normal man. Considering the usual ratio of three nonerythroid to one erythroid cell (Table 2-1) this suggests that there is an average of approximately  $14 \times 10^9$  nucleated marrow cells/kg. Donohue and co-workers<sup>64</sup> studied radioactive iron localization in marrow of ribs removed at thoracotomy and calculated an average of  $18 \times 10^9$  nucleated marrow cells/kg. Total marrow mass can be calculated from the rate of turnover of mature blood cells if the relation of turnover to the number of marrow precursor cells has been established (see Chapter 6 for an example of calculation of neutrophil mass). Harker<sup>93</sup> carried out such studies for platelets and megakaryocytes and arrived at figures which correlated well with those given above. By making a variety of assumptions concerning the structure of marrow compartments for neutrophils, a figure of  $18 \times 10^9$  nucleated marrow cells/kg was derived.<sup>23</sup>

#### Weight of Bone Marrow

It has been calculated from autopsy studies that the weight of marrow tissue approximates 3.4 to 5.9% of total body weight in the adult or 1600 to 3700 g.<sup>138</sup> Thus, the weight of marrow is roughly equivalent to that of the liver.

#### Functional Capacity of the Bone Marrow

A very large increase in production of all marrow cells can be induced not only by diseases such as polycythemia vera (Chapter 30) but also in response to increased cell demands fostered by excessive cell loss as is observed in patients with hemolytic anemia (Chapter 21), chronic infection (Chapter 42), or idiopathic thrombocytopenic purpura (Chapter 34).

Expanded production can be accomplished by increased parenchymal cellularity with loss of fat in areas of normal hematopoiesis,<sup>39</sup> expansion of hematopoietic marrow into previously inactive fatty marrow cavities, short-

ening of cellular maturation time, and perhaps by accelerating generation time. In general, production can be accelerated to a much greater degree in response to a long-standing chronic stimulus than to an acute stimulus.<sup>53</sup>

In rabbits with chambers implanted in bone the following sequence of conversion from nonhematopoietic to hematopoietic marrow has been observed: resorption of some bony trabeculae, growth of arterioles into the cavity from bone, sinus formation, and finally formation of islands of hematopoiesis.<sup>135</sup> In man, increased cell production as observed in association with leukemia, is accompanied by a selective increase in blood flow to the marrow.<sup>167</sup>

Erythrocyte production has been calculated as six to twelve times normal in persons with congenital spherocytic hemolytic anemia (Chapter 21). Platelet production has been calculated as being as high as eight times

normal in those with idiopathic thrombocytopenic purpura (Chapter 34). Neutrophil production may be four times normal in patients having chronic infection (Chapter 42). The relative importance of the various mechanisms for increasing cell production mentioned above has not been determined, but an increase in the total number of precursors appears more crucial than shortening of stem cell to mature cell maturation time.<sup>91</sup> Temperature of marrow cavities (which would presumably in part be secondary to blood flow) has been suggested as a factor regulating fatty versus hematopoietically active marrow.<sup>57</sup> While it is true that marrow activity is favored when rodent vertebrae are transplanted from the tail (cold) to the peritoneal cavity (warm), it appears that physiologic stimulation, as with high erythropoietin levels, is required to produce conversion from fatty to hematopoietically active marrow.<sup>127</sup>

Increased production of one cell line is not

accomplished at the expense of another except under unusual experimental circumstances. In mice recovering from irradiation with a consequent reduction in the size of the stem cell pool there may be "competition" for available stem cells.<sup>43,97</sup> In such animals, if an abnormal demand for erythrocytes (bleeding, erythropoietin injection) is imposed, granulocyte production is decreased even further; the converse is true in plethoric animals. However, with normal stem cell pools, simultaneous demands for increases in output of various cell lines can be met. For instance, after normal animals are bled, red cell, neutrophil, and platelet production are increased simultaneously.<sup>84</sup>

## Methods of Obtaining Bone Marrow Specimens

Normal bone marrow is soft and semifluid during life and consequently can be removed for examination by aspiration as well as by biopsy techniques. Marrow biopsy was performed in 1903 by Pianese, who punctured the epiphysis of the femur by means of a trocar, and in 1908 by Ghedini, who trephined the tibia in its upper third.<sup>190</sup> In 1923, Seyfarth<sup>190</sup> trephined the sternum, choosing it because of accessibility, the thinness of the bone, and the likelihood of finding active marrow at this site throughout life. Needle aspiration of the bone marrow was proposed by Arinkin<sup>8</sup> in 1929 and since that time this procedure has gained preference over open surgical biopsy. Open surgical bone marrow

biopsies have now been largely supplanted by needle biopsy when information beyond that which can be obtained by examination of aspirated material is desired (page 75). A number of monographs dealing with the subject of bone marrow study have been published.<sup>29,56,116,177,189,190,193</sup>

### Aspiration of Bone Marrow

Many types of needles have been used for marrow aspiration. Needle gauges ranging from  $\#14$  to  $\#18$  have been fully satisfactory in our experience. Compared with the larger needles, the smaller ones have the slight advantage of easier penetration of bone, but the disadvantage of being bent or deformed more easily while penetrating the bone. Adjustable guards which limit the depth of penetration may be desirable for operators without extensive experience in marrow aspiration. A satisfactory needle is shown in Figure 2-12.

Various sites may be used for puncture and aspiration. In adults, all things being equal, the sternum at the second intercostal space is the most satisfactory. The likelihood of obtaining a satisfactory cellular aspiration is greater at this site than from the iliac crest or other areas, and the thinness of the sternum adds to its suitability. Aspiration should not be attempted from the body of the sternum below the second intercostal space. At lower levels the great vessels and right atrium present a hazard. If one has the misfortune of penetrating the inner table, severe or even fatal hemorrhage and/or pericardial tampon-

Fig 2-12. University of Illinois Stereal Needle with adjustable guard, special locking device for the stylet and Luer-Lok hub set into the needle. (Courtesy of V. Mueller and Co., Chicago)

ade may result.<sup>10</sup> To our knowledge these are the only causes of mortality reported from needle aspiration or biopsy of the marrow. We have observed serious infections in neutropenic patients at the site of open surgical biopsy but rarely at sites of needle aspiration or biopsy. The space behind the second intercostal space contains fat and lymph nodes primarily. In the unfortunate event of mediastinal penetration, some degree of mediastinitis or pneumomediastinum is the worst complication that can be expected.

The operator should scrub prior to aspiration and puncture as for any surgical procedure and in some instances he should wear surgical gloves. To exceedingly apprehensive patients, sedation may be administered in advance of the procedure. The area of skin to be punctured is washed, shaved if considered necessary, an antiseptic is applied, and sterile towels are laid closely around the site. The skin and the periosteum must be anesthetized if severe pain is to be avoided. Since the tissue lying between skin and periosteum is virtually devoid of painful nerve endings, infiltration of this intervening tissue is unnecessary. With a hypodermic needle of approximately 25 gauge, the most superficial layer of skin is infiltrated with procaine; the needle is next advanced until the bone is touched. At this point, procaine is injected in order to obtain anesthesia of the periosteum. If a guard regulating the depth of penetration is to be used, the distance required to reach the sternum by the infiltrating needle is measured and an additional distance is added to include penetration of the outer table of the sternum. This outer table varies considerably in thickness, ranging from 0.2 to approximately 5 mm.

The marrow aspiration needle is passed vertically, with a slight rotating or boring motion, into the sternum between the second and third ribs in the midline or slightly to the side of the midline. Rotation of the needle aids penetration; a "give" is felt when the marrow cavity is entered. The cavity is normally 5 to 15 mm in depth which permits the needle to be passed another 1 or 2 mm after the "give" has been felt.

When the marrow cavity has been entered, the stylet is removed from the needle and a sterile syringe is attached. The size of syringe is unimportant as long as it is well fitting, thus providing significant pressure for aspiration. The plunger is slowly withdrawn until the first drop of marrow appears in the syringe. The syringe should be removed at this point and, if for any reason a larger volume of marrow is desired, this should be collected in a second syringe. The patient usually experiences momentary pain when suction is applied, provided the needle is in the marrow cavity. If no marrow is obtained the needle should be successively rotated, advanced, and retracted, and suction again applied. If this proves unsuccessful, it is probably best to try another site. Pressure for a few moments over the site of aspiration usually obviates any bleeding from the puncture site. However, if bleeding does occur, a tight dressing should be applied.

Other sites satisfactory for aspiration of the marrow include the iliac crest, posterosuperior iliac spine, spinous process, rib,<sup>115,177</sup> and, in infants, the head of the tibia. The same procedure outlined for the sternum is followed when any of these sites is selected. For aspiration from the iliac crest, the anterosuperior spine of the crest should be identified by palpation and a site for aspiration chosen 1 to 2 inches posterior to this and just under the palpable lip of the crest. The needle is then directed so as to penetrate the crest area from below the lip. For posterosuperior iliac spine aspiration, the needle is directed vertically into the center of this oval protuberance (Fig. 2-13). For spinous processes, the third or fourth lumbar vertebra usually is chosen and the patient may assume a sitting position if desired. The needle should be directed so as to anticipate following the axis of the spinous process. In children under two years of age, the flat triangular area at the proximal end of the medial surface of the tibia, just below the tibial tubercle and medial to the tibial tuberosity, may be punctured. However, even in young children the posterosuperior iliac spine or the iliac crest is quite satisfactory. Because ster-

Fig. 2-13. Westerman-Jensen technique for needle biopsy of bone and marrow. A, Biopsy needle and outline of steps in its use. B, site of biopsy (From Ellis, L. D. et al.,<sup>67</sup> courtesy of authors and American Medical Assn.)

nal aspiration often frightens young children it should be avoided.

Inherent in considering alternate anatomic sites as suitable for aspiration is the assumption that active marrow contains the same proportion of cells in all anatomic sites. Comparison of sternum, ribs, vertebrae, femur,<sup>116-199</sup> and iliac crest of adults,<sup>181</sup> and sternum, tibia, femur, and vertebrae of infants<sup>80,209</sup> suggests that this assumption is correct in normal subjects.

### Biopsy of Bone Marrow

When aspiration of marrow provides inadequate material ("dry tap") or in certain clinical situations in which one may anticipate additional information when a larger specimen is obtained (page 75), biopsy should be performed. Such biopsies are carried out by using various modifications of the Vim-Silverman needle<sup>136</sup> such as that of Westerman and Jensen.<sup>67</sup> Needles with larger bores or with multiple openings are also available.<sup>142-172</sup> A needle designed to avoid "crush artifact" which is sometimes a problem with the above needles has been described.<sup>101</sup> The Westerman-Jensen needle is supplied with finger grips, an assembly stylet, and an obturator which locks in position (Fig. 2-13A).

The posterosuperior iliac spine is the most commonly used site for biopsy. The patient is placed in a lateral recumbent position. The needle, with the obturator locked in place, is inserted into the previously anesthetized skin overlying the posterosuperior iliac spine (Fig. 2-13B). It is inserted through the skin and bone cortex by using a rotating movement. Once the medullary cavity has been reached, the stylet is unlocked and removed. The cutting blades, with the assembly stylet in place, are inserted into the outer cannula, the assembly stylet is removed, and the blades are advanced until the medullary bone has been entered. The cutting blades are pressed into the medullary bone while the outer cannula is held firmly in a stationary position. The outer cannula is then advanced over the cutting blades, thus trapping the tissue, and the entire unit is then removed. The specimen

is separated from the cutting blades by teasing it from the tip before withdrawing the blades through the cannula.

Optimal specimens are approximately  $\frac{3}{16}$  inch long,  $\frac{1}{16}$  to  $\frac{1}{8}$  inch in diameter, and have wet weights of about 150 mg. Cultures, imprints ("touch preparations"), and histologic sections are prepared, as discussed below.

Post-biopsy care ordinarily consists of applying pressure over the posterior ilium for about 60 minutes. Pressure is obtained by means of a pressure dressing and by having the patient lie recumbent in bed. Patients with a bleeding tendency or other complications are carefully observed for a longer period. Analgesics are seldom necessary after the procedure.

## Preparation of Bone Marrow Specimens

### Smears

The best smears are made by placing a macroscopic marrow particle from the aspirate between scrupulously cleaned coverslips, squashing the particle between the coverslips with very slight pressure, and then pulling the coverslips gently apart so that the particle is smeared onto both of them. For this purpose, the small amount of material aspirated into the first syringe may be expressed onto a watch glass or onto a slanted glass slide and the visible particles picked up with either a pipet or a corner of a coverglass. If particles are not visible in the aspirated material, a small drop of the material should be placed between the coverslips and prepared as one would prepare a blood smear (Chapter 1). Smears from the aspirated material must be prepared promptly to avoid clotting, although they may be prepared more leisurely if the aspirate has been anticoagulated. However, all available anticoagulants introduce some artifactual change in the structure of marrow cells. Of those presently available, ethylenediamine tetraacetic acid (EDTA) introduces fewer artifacts and thus is the anticoagulant of choice. Slides may be stained with Wright's stain or with a May-Grun-

wald-Giemsa stain, depending on individual preference. The routine use of an iron stain, such as the Prussian blue, for marrow smears also is recommended (page 628). In addition, one may wish to stain for peroxidase or alkaline phosphatase.

### Supravital Preparations of Marrow

Supravital staining offers an opportunity to study motile cells that are partially stained. On slides prepared with a dry film of stain, a portion of marrow, preferably a macroscopically visible particle, is flattened under a coverglass by gentle pressure. The coverglass is then sealed along its edges to the underlying slide with petroleum jelly. The living cells can then be observed. When examined by skilled observers, this preparation in conjunction with the study of smears stained with Wright's stain may provide added information, as, for example, in differentiating types of acute leukemia. (Chapter 47).

### Concentrated Preparations<sup>19</sup>

When few cells are found in the smears made from freshly aspirated specimens, it may prove useful to concentrate cells from an anticoagulated portion of the aspirate. This marrow can be centrifuged in tubes of small diameter such as the Wintrobe hematocrit tube. Fat, plasma, nucleated cells, and red cells separate into visible layers and smears are prepared from the nucleated cell layer. As previously noted, anticoagulation may lead to cell artifact. Consequently, subtle changes on such smears must be interpreted with caution. Furthermore, since cells of different density sediment in different regions of the nucleated cell layer, the differential count may be inaccurate.

### Preparation of Sections from Biopsy Specimens

Various means for making sections from clots or material concentrated from aspirated marrow have been described.<sup>5,19,20,21,157,158</sup> These sections often provide information be-

yond that obtained by examination of smears.<sup>118</sup> However, with the introduction of relatively simple means of obtaining a needle biopsy specimen (Fig. 2-13), if sections are desired, this procedure rather than section of clots obtained by aspiration should be employed. Biopsy specimens are placed directly in Zenker's acetic acid solution and processed in routine fashion prior to staining. Staining with hematoxylin and eosin, with Giemsa, and with iron stains is carried out routinely. Modified thin-section preparation methods such as that of Block and associates<sup>21</sup> allow more accurate identification of individual cells in sections than do routine preparations.

### Touch Preparations

The freshly obtained biopsy specimen can be picked up with forceps and gently applied to a clean glass slide by repeatedly touching the slide with the specimen. Touch preparations yield more certain identification of individual cells than do biopsy sections and are less likely than marrow smears to disrupt syncytial masses or compact clusters of cells.

## Examination of Bone Marrow Specimens

Information that can be derived routinely from examination of the marrow includes estimation of cellularity, detailed cellular structure, estimation of iron stores, and determination of the presence or absence of tumor cells, storage cells, and granulomas. Normal values are presented and indications for aspiration and/or biopsy will be discussed here, but details of abnormal findings in specific diseases will be given in later chapters.

### Estimation of Cellularity

Absolute counts of nucleated cells from marrow aspirates<sup>174</sup> are of little value because wide fluctuations in cell concentration are produced by aspiration of variable amounts of blood with marrow. Accurate techniques are available for estimating total nucleated cells in the bones of small animals,<sup>17</sup> but

Fig 2-14 Tumor cells in bone marrow smears. A and B, mucus-producing cells from a patient with bronchogenic carcinoma. C, mucoid carcinoma of the colon. D, hypernephroma. E and F, small and large cell metastases from neuroblastomas. All  $\times 380$ .

these are not applicable to man. Examining smears of aspirated marrow gives little information concerning total cellularity of the marrow. One can state that the *smear* is rich in cells or relatively acellular, but to draw inferences concerning *marrow* cellularity from smears is hazardous. Somewhat more reliable information concerning marrow cellularity is obtained by examining sections made from biopsy specimens. In such specimens, fat spaces and hematopoietically active

parenchyma normally exist in a ratio ranging from 1:1 to 2:1 in adults. Deviation beyond these limits suggests that the marrow is hypoplastic or hyperplastic with respect to hematopoiesis. However, it must be remembered that such a biopsy specimen represents but an infinitesimal fraction of the total marrow. There is evidence for fairly even distribution of the *proportion* of various cell types throughout the marrow (page 69), but whether total cellularity is evenly distrib-

uted throughout the marrow is less certain. Significant variation in cellularity in different portions of large sections from the iliac crest has been reported.<sup>91</sup> If total cellularity is an important concern in the diagnostic or therapeutic considerations, then one of the techniques for estimating total marrow mass (page 61) should be considered. The use of the myeloid to erythroid ratio (M:E) in estimating cellularity is discussed on page 71.

### Cells of the Normal Bone Marrow

Cellular identification is much more certain in properly prepared smears from aspirated marrow than in sections of biopsied marrow.

#### Megakaryocytes

Concentration should be estimated in smears of aspirated material and/or in sections of biopsied material by scanning the preparations under low-power magnification (for example, at 100 $\times$ ). In specimens rich in normal hematopoietic tissue, these giant cells (Plates VIII, XIV) should be found easily in each field. Low-power scans should also be carried out routinely for the purpose of detecting clusters of tumor cells or granulomas (Figs. 2-14 and 2-15 and Plate XXIV).

#### Marrow Differential Count

This is carried out by examining a minimum of 300 to 500 nucleated cells under oil-immersion magnification. Care must be taken to examine well-spreadout, well-stained areas in which few ruptured cells ("bare nuclei") are present.

Values for the percentage of various cells in marrow vary rather widely in reported series. This could be attributed to differing morphologic definitions of cells, variations in amount of contamination by blood leukocytes, the inclusion or exclusion of areas with many ruptured cells, and inclusion of sick patients with "normal blood" as sources of normals. Results of differential counts from smears prepared from marrow particles

obtained by sternal aspiration (page 63) from 12 healthy men are given in Table 2-1. These values are not presented as "exact" normals but as a guideline for what may be expected. They differ from those summarized by Osgood and Seaman<sup>156</sup> only in the slightly lower percentage of segmented neutrophils and a higher percentage of nucleated erythrocytes. Custer<sup>56</sup> reported a higher percentage of myelocytes and a much lower percentage of lymphocytes than are shown in Table 2-1.

Glaser and associates<sup>86</sup> and Sturgeon<sup>200</sup> as well as others<sup>63,80,192,214</sup> reported extensive studies of marrow aspirates from normal infants and children. These studies are summarized in Table 2-2. At birth there are few lymphocytes in marrow aspirates but by one week of life an increasing percentage of lymphocytes is noted. A third to more than half the marrow cells are lymphocytic during the remainder of the first year of life, but their percentage declines to approach adult levels by the age of four years. During the first week of life the percentage of erythrocytic precursors declines quite rapidly because of lack of erythropoietic stimulation (page 56). Thereafter the M:E ratio remains essentially the same throughout infancy and childhood and into adult life. There is a tendency for eosinophils to be increased in young children. Plasma cells are rarely observed in the marrow of newborn infants but appear during the first few months of life (Chapter 7).

In our series (Table 2-1) as well as in most studies which provide the necessary raw data, the distribution of the percentage of various cell types is gaussian except for plasma cells and perhaps for lymphocytes. The distribution of both of these cell types tends to be skewed toward high values. This suggests that lymphocytes and plasma cells are more unevenly distributed in the marrow than are other cells. This postulate tends to be borne out by examination of sections of biopsy specimens in which irregularly spaced lymphocytic nodules may be discerned<sup>193</sup> and in which plasma cells tend to be associated with blood vessels.

Fig 2-15. Granulomatous lesions in sternal bone marrow. A, Miliary tuberculosis ( $\times 205$ ), B, sarcoidosis ( $\times 225$ ), C, Hodgkin's disease ( $\times 285$ ), D, infectious mononucleosis ( $\times 350$ ), E, granulomatous hepatitis ( $\times 235$ ), F, acquired hemolytic anemia, history of undulant fever seven years before ( $\times 145$ ), hematoxylin and eosin stain (From Pease,<sup>168</sup> courtesy of author and Grune & Stratton)

Table 2-2. Changes in Differential Counts of Bone Marrow with Age

		Birth	1 Week	1 Week to 1 Year	1-4 Years	4-12 Years	Adult
Neutrophilic series	$\bar{x}\%$	54	65	37	50	52	57
	95% limits	31-77	21-79	22-52	32-68	35-69	39-79

M:E ratio	$\bar{x}$	1.6	4.3	2.2	2.6	2.5	2.6

The means ( $\bar{x}$ ) and 95% confidence limits in this table were calculated by combining data published by Osgood and Seaman<sup>154</sup> Sturgeon<sup>200</sup> Shapiro and Bassen<sup>192</sup> Veeneklaas and associates<sup>214</sup> and Olwany,<sup>43</sup> and the data in Table 2-1

### Normal, Nonhematopoietic Cells (Plate 1)

These include reticulum cells, osteoblasts, osteoclasts, and Schwann cells.

*Reticulum cells* range between 20 and 30  $\mu\text{m}$  in diameter (Plate XXIV, F). Their cytoplasm is pale, basophilic, and abundant, and may contain a few azurophilic granules. The nucleus is large, round, or oval and presents a pale-staining, fine, lace-like chromatin pattern and one or more round or oval nucleoli.

*Osteoblasts and osteoclasts* must be differentiated from the hematopoietic cells of the bone marrow since they may be mistaken for cells of the plasmacyte series and megakaryocytes, respectively, or even for tumor cells invading the marrow. *Osteoblasts* are oval cells, sometimes elongated, 25 to 50  $\mu\text{m}$  in diameter, with rather blurred outlines. The cytoplasm may take a light-blue or sometimes a dark-blue stain, may contain a few azurophilic granules, and occasionally is fenestrated. As a rule the nucleus lies eccentrically and is composed of clumped or trabeculated chromatin and distinct parachromatin. It contains from one to three nucleoli. *Osteoclasts* are giant, polyploid cells with indistinct cytoplasmic borders, their diameters often exceeding 100  $\mu\text{m}$ . The cytoplasm is cloudy and finely granular in the marginal portions

and may stain from weakly basophilic to strongly acidophilic. It may contain numerous azurophilic granulations of various sizes. The nuclei of these polyploid cells are scattered throughout the cell, usually not touching one another. The nuclear chromatin is dense, but one nucleolus is usually present in each nucleus. *Osteoblasts and osteoclasts* are seen most frequently and in largest numbers in fetal marrow. In disease, they have been observed especially frequently in association with metastatic malignant lesions, acute leukemia, myelofibrosis, and secondary osteoporosis.<sup>92</sup>

*Schwann cells* may be observed in sections from biopsy specimens and probably are related to the innervation of bone marrow. They have not been described in aspirated material.<sup>37</sup>

### Necrotic Marrow

Necrotic marrow may be obtained from patients with leukemia, lymphosarcoma, or other forms of tumor invading the marrow.<sup>2,33</sup> This is easily recognized in marrow sections<sup>2</sup>; in smears the marrow cells appear smudged and are surrounded by slightly acidophilic, granular masses.<sup>33</sup>

### Myeloid-to-Erythroid Ratio

This ratio is derived by relating the percentage of neutrophils and neutrophil pre-

cursors to the percentage of nucleated erythroid precursors. Whether eosinophils and basophils are or are not included in the "myeloid" percentage is usually of little consequence. We prefer to exclude these cells since their production appears to be controlled independently of the neutrophilic series (Chapter 6). Some hematologists prefer to exclude mature neutrophils from the ratio, an exclusion which significantly lowers the "normal limits."<sup>57</sup> The extremes of M:E ratios in our studies of the marrow of 12 normal men were 1.5:1 and 3.3:1, with a mean of 2.3:1 (Table 2-1). Inferences concerning the total number of myeloid or erythroid cells in the marrow can be made from

this ratio provided there is evidence that one of the systems is normal. For example, if blood neutrophil concentration and cell structure are normal and if the ratio of various neutrophil precursors in marrow to one another is normal, it can be assumed this is a normal system. In this circumstance an increase in the M:E ratio implies decreased nucleated red cells and decreased red cell production; a decreased M:E ratio implies the converse. However, if both systems are abnormal, no estimates of total production in either system are justified from the M:E ratio. Examples of the anticipated changes in M:E ratios in various diseases are shown in Table 2-3.

Table 2-3. Representative Differential Counts of Bone Marrow Obtained by Puncture

Types of Cells	Leukemia, Acute <sup>a,b</sup>	Leukemia, <sup>b</sup> Chronic Myelocytic	Leukemia <sup>b</sup> Chronic Lymphocytic	Multiple Myeloma <sup>c</sup>	Pernicious Anemia	Hemolytic Anemia	Iron Deficiency Anemia	Purpura Hemorrhagica <sup>d</sup>

Pronormoblasts			0 2			5 0		4 0
Normoblasts		2 4	14 3	9 0	3 0	43 0	40 0	36 0
Myel eryth (M:E) ratio		40:1	15:1	8:1	1:15	1:1	14:1	15:1

<sup>a</sup>The immature forms are listed in the table as myeloblasts merely as a matter of convenience. In acute lymphoblastic leukemia the cells are lymphoblasts, not myeloblasts. Often it is difficult to distinguish the various immature leukocytic cells seen in acute leukemia. The essential point is the great preponderance of very young forms.

<sup>b</sup>The bone marrow picture in *aleukemic leukemia* is similar to that of leukemia of the various types, whether or not changes can be demonstrated in the blood.

<sup>c</sup>The characteristic cells in multiple myeloma differ somewhat from typical plasma cells in that the nuclear chromatin is relatively fine and the wheel spoke arrangement of the chromatin is not present, the cytoplasm is basophilic and bright blue, not blue-green as in the plasma cell. A perinuclear clear zone is unusual.

<sup>d</sup>Although the number of megakaryocytes may not appear to be increased in typical purpura hemorrhagica the majority (64% in the patient cited) have no platelets about them and most of the remainder (32%) have very few.

# PLATE II

Giant cells found in the bone marrow (photomicrographs, Wright's stain,  $\times 1000$ ). A, Osteoblasts. B, multinucleated osteoclast; C, D, E, macrophages. F, "sea-blue" macrophage from a patient with chronic myelocytic leukemia. G, Gaucher cell, H, Niemann-Pick cell. Contrast these cells with the megakaryocytes shown in Plate VIII

## Hemosiderin in Bone Marrow

Examination of the bone marrow for iron is valuable in determining the adequacy of body iron stores. Several techniques are available. Particles of marrow, smeared on coverglasses, may be examined without staining.<sup>173</sup> After locating marrow tissue under low-power magnification, the particle is examined under oil-immersion magnification. Hemosiderin appears as golden yellow, refractile granules ranging from a fraction of a micron ( $\mu\text{m}$ ) to several micra in size. Marrow hemosiderin is more easily discerned by staining smears from aspirates or sections from biopsies with Prussian blue.<sup>67</sup> Large granules or aggregates of blue-staining iron may be observed within reticuloendothelial cells or they may appear to be lying free between cells in aspirated material. Smaller granules can be seen within developing red cells (sideroblasts) in properly prepared smears of normal marrow.<sup>107</sup> The significance of the proportions of nucleated red cells which are sideroblasts as well as the significance of reduced or increased iron in marrow are discussed in Part III, Section 3.

## Indications for Marrow Aspiration

Marrow aspiration is at all times interesting and often affords a more complete picture of the reaction of the hematopoietic tissue than can be gained from the blood sample alone.<sup>70,116,166</sup> However, it yields information of crucial importance in a limited number of conditions.

### Anemia

#### *Megaloblastic Anemias (Chapters 14 and 15)*

This type of anemia usually is evident from examination of the blood smear, but examination of aspirated marrow provides confirmation, if needed. Little, if any, diag-

nostic information is gained by examining the marrow of patients with nonmegaloblastic macrocytic anemias. An example of the expected findings in the marrow of patients with pernicious anemia is shown in Table 2-4.

#### *Hypochromic, Microcytic Anemias (Chapters 16, 17, and 18)*

Iron stains of aspirated material are useful when the diagnosis is not clearly established from the blood smear and from the iron and transferrin levels in serum. In patients with the rare sideroblastic anemias, the demonstration of iron granules "ringing" the nucleus of the nucleated red cells is essential to the diagnosis. In marrow smears treated with Wright's stain, a decreased M:E ratio often is observed in specimens from patients with iron deficiencies (Table 2-4).

#### *Hemolytic Anemias (Chapter 20)*

Marrow examination is of no diagnostic value except to confirm the presence of increased erythropoiesis in response to hemolysis (Table 2-4). Marrow aspiration can be useful in distinguishing "aplastic" from "hemolytic" crises as a cause of increasing anemia in patients with these diseases.

#### *Normochromic, Normocytic Anemias (Chapter 19)*

Marrow aspiration is essential to diagnosis of the rare state of "pure red cell aplasia." However, routine marrow examination is of minimal value in patients with other such anemias unless the condition is secondary to a neoplastic or granulomatous disease, in which instance a biopsy should be performed (see below).

#### *Neutopenia (Part V, Chapter 41)*

Marrow aspiration is useful in observing the relationship between various neutrophil precursors and determining the M:E ratio.

**Table 2-4. Conditions in Which Various Types of Reaction May be Observed, as Demonstrated by Bone Marrow Aspiration**

<i>M E ratio increased</i>	<i>Nonmyeloid cells increased</i>
Myeloid forms of leukemia	Other forms of leukemia
Majority of infections	Multiple myeloma
Leukemoid reaction	Metastases from carcinoma, etc
Decrease in nucleated red cells	Gaucher's disease, Niemann-Pick disease
	Aplastic anemia (usually relative increase only)
	Infectious mononucleosis
<i>M E ratio normal</i>	
Normal marrow	
Myelosclerosis	
Multiple myeloma, etc	
Aplastic anemia	
	<i>M E ratio decreased</i>
	Decrease in myeloid cells (agranulocytosis)
	Increase in erythroid cells due to either
<i>Normoblastic hyperplasia</i>	<i>or Megaloblastic hyperplasia</i>
Hemorrhagic anemias	Pernicious anemia
Iron deficiency anemia	Sprue, idiopathic steatorrhea, resection of small intestine (certain cases)
Hemolytic anemias	Tropical macrocytic anemia
Thalassemie	Nontropical nutritional macrocytic anemia
Cirrhosis of the liver	Macrocytic anemia with <i>Diphyllobothrium</i> infestation
Polycythemia vera	Megaloblastic anemia of infancy
Plumbism	Megaloblastic anemia of pregnancy
Anemia of chronic renal disease	Refractory megaloblastic anemia
	Achrestic anemia

### Leukemias (Part V, Chapters 46-49)

Marrow aspiration is a necessary diagnostic method in patients with acute leukemia who have few or no blast forms in the blood.

Marrow aspiration is of no diagnostic value in patients with the chronic leukemias whose blood is diagnostic except as a source of cells for cytogenetic search for the Philadelphia chromosome.

Examples of marrow findings in leukemia patients are given in Table 2-4.

### Thrombocytopenia (Chapter 34)

Marrow aspiration is useful in estimating whether megakaryocytes are increased, normal, or decreased. In the usual patient with idiopathic thrombocytopenic purpura, they are increased (Table 2-4).

### Immunoglobulin Disorders

(Part V, Chapters 44, 45, 52, and 53)

Marrow aspiration is useful in demonstrating increased and sometimes abnormal-appearing plasma cells (Table 2-4) and lymphocytes in patients with immunoglobulin-producing tumors as well as in demonstrating absent or decreased plasma cells in those with the hypogammaglobulinemic syndromes.

### Miscellaneous Conditions

Certain diseases in which the diagnosis can be made from marrow, but not from blood, are Gaucher's disease (Plate II, G), Niemann-Pick disease (Plate II, H), and kala azar. Sometimes malarial parasites may be found by marrow aspiration when they cannot be demonstrated in blood.<sup>101</sup>

# PLATE III

A

B

**Bone marrow biopsies in different conditions (Giemsa stain)** A. Normal bone marrow ( $\times 100$ ) B. erythroid hyperplasia in a patient with hereditary spherocytosis ( $\times 400$ ) C. aplastic marrow of a patient irradiated for pelvic carcinoma ( $\times 100$ ) D. myelofibrosis ( $\times 100$ ) E. F. Hodgkin's disease (E.  $\times 100$ , F.  $\times 400$ ) G. Reed Sternberg-like cell ( $\times 1000$ ) H. Poorly differentiated lymphocytic lymphoma ( $\times 100$ ) (Courtesy of Dr Robert E. Lee)

Conditions in which marrow examination is of little or no diagnostic value include polycythemia (Chapter 30) and infectious mononucleosis (Chapter 43).

## Indications for Bone Marrow Biopsy

Marrow aspiration entails less discomfort and expense for the patient than does marrow biopsy. Consequently, biopsy should not be performed unless information additional to that obtained from aspiration is anticipated. Even if biopsy is carried out, a smear of the marrow should be made from a drop from the needle because this will be helpful in morphologic examination. In general, biopsy is indicated under the following circumstances:

1. Repeated failure to obtain adequate material by aspiration.

2. Evaluation of pancytopenia or bicytopenia. The evaluation of total cellularity afforded by biopsy (page 68) usually justifies its routine use when more than one type of blood cell is reduced. If only one cell line is reduced, similar information often can be gained from the M:E ratio (page 71).

3. With any blood changes raising the question of myelofibrosis (Chapter 57). In this circumstance, biopsy is required for confirmation since fibrosis cannot be demonstrated with certainty on smears from aspirations.

4. Any circumstance in which the question of metastatic tumor, lymphoma, or granulomatous disease of marrow can be raised. Tumor cells and even granulomas may be observed in aspirated material, but they are more easily found in sections from biopsy specimens.<sup>217</sup> Furthermore, since the *in situ* architecture of the marrow is better preserved in biopsied than in aspirated material, the identification of the lesion is aided by biopsy. Tumor cells, metastatic from carcinoma of the prostate,<sup>182</sup> breast, lung, kidney, and other tissues,<sup>67</sup> as well as in neuroblastoma<sup>79</sup> and rhabdomyosarcoma,<sup>61</sup> have been demon-

strated, even by marrow aspiration.<sup>147,208</sup> They are often found in groups or clumps (Fig. 2-14 and Plate XXIV). The cells usually are large, with vesiculated nuclei and scanty cytoplasm. The cytoplasm may be basophilic and mitotic figures may be found. One or more prominent nucleoli frequently are visible.

In sections of bone marrow it has been possible to demonstrate lesions of brucellosis,<sup>201</sup> miliary tuberculosis,<sup>187</sup> histoplasmosis,<sup>166</sup> and sarcoidosis,<sup>19</sup> as well as Hodgkin's disease<sup>67</sup> (Fig. 2-15).

### **Discovery of the Erythrocyte and Early Studies**

"Small round globules" were described in human blood by the Dutch microscopist, Leeuwenhoek, in 1673, but the "ruddy glob-

ules" were probably first observed by Swammerdam 15 years earlier. Malpighi (1665) mistook them for fat globules "looking like a rosary of red coral." Leeuwenhoek made a thorough study of these red bodies, and attributed the color of blood to them.

One hundred years later, William Hewson recognized that these particles are really flat discs rather than globules and suggested that they "must be of great use" in the body economy. The presence of iron in blood was demonstrated by Menghini in 1747, and Funke isolated hemoglobin in crystalline form in 1851. It was not, however, until 1867 that Hoppe-Seyler demonstrated that hemoglobin has the property of readily taking up and discharging oxygen. It was then that the functional significance of hemoglobin and of the particles in which it is carried became clear.

During the latter half of the 19th century, many studies of the erythrocyte were made. Vierordt (1852) and Welcker (1854) made the first blood counts. Their laborious technique was considerably improved by the invention of the counting chamber and diluting pipet. At the same time, attention was given to methods for measuring the coloring matter of the blood. Vierordt devised a spectroscopic method and Welcker described a colorimetric method. In the first monograph on hemoglobin, Preyer, in 1871, referred to several spectroscopic, chemical, and colorimetric methods.<sup>15</sup>

Neumann, in 1868, demonstrated that the red corpuscles are formed in bone marrow, arising there from colorless, nucleated elements.<sup>25</sup> With the introduction of the anilin dyes which followed Ehrlich's studies of 1877 and later, the morphologic study of the blood and tissues received attention. At the same time, interest was aroused in the variations in the size and hemoglobin content of erythrocytes in anemia and in methods for their measurement. These will be described later.

## Normal Development of the Erythrocyte

### The Erythron

Blood cells differ from the great majority of body tissues in that the mature, functioning cells are physically separated from their precursors. With respect to erythrocytes, it is useful to conceive of the precursor and mature cells as components of a single, though discontinuous, organ known as the "erythron."<sup>3</sup> This concept emphasizes the functional unity of the red corpuscles and their precursors. The erythron has been compared to the skin which evolves through layers of cells of increasing maturity, to a layer of essentially inert but functionally important cells, those of the corneum.<sup>41</sup> In the same way

one may think of the erythron with its primitive normoblasts giving rise eventually, after a series of changes, to the non-nucleated, highly specialized red corpuscles. The interstitial tissue of the erythron is represented by the plasma and by the fat and reticulum of the bone marrow. When considered as a whole, the erythron is an organ much larger than the liver (Fig. 3-1). The concept of the erythron as an organ unit contributes also to the understanding of pathologic changes in red cells (Chapter 13, page 529).

### Morphologic Aspects of Erythropoiesis

#### Nucleated Erythrocyte Precursors

*Erythroblast* was a term used by Ehrlich to refer to all forms of nucleated red cells, pathologic as well as normal. He classified erythroblasts into two main categories: a normal series, the *normoblasts*, and a pathologic series, the *megaloblasts*. The latter he had observed in pernicious anemia during relapse, as well as in early embryonic blood. Certain workers, however, notably Sabin and her school, used the term "megaloblast" to refer to a large and primitive, but normal, erythrocyte precursor. The term "megaloblast" will be used in this book in the pathologic sense given it by Ehrlich and followed by Naegeli, Ferrata, Downey, Jones, and others.<sup>25</sup> These

Fig. 3-1. Scale model of the erythron.<sup>8</sup> The relative proportions of each of the components are shown. The numbers below each box indicate the average number of cells per kilogram of body weight.

abnormal cells will be described and discussed in Chapter 14.

The existence of primitive hematopoietic stem cells of both pluripotential and unipotential varieties has been discussed in Chapter 2 (page 49). However, such cells have not been identified morphologically. The least mature, recognizable erythrocyte precursor cell is known as the *pronormoblast*. Cells characteristic of subsequent stages of maturation are termed *basophilic normoblasts*, *polychromatophilic normoblasts*, *orthochromatic normoblasts*, *reticulocytes*, and *mature erythrocytes*. A variety of synonymous terms have been applied by various authors (these will be given, in parentheses, with the descriptions of the stages which follow). The morphologic characteristics of each of these normal stages of erythrocyte maturation have been defined chiefly on the basis of observations with light microscopy. These characteristics will be described in the ensuing paragraphs, a description of additional findings on electron microscopy will follow (page 84).

The pronormoblast (proerythroblast of Ferrata, lymphoid hemoblast of Pappenheim, "rubriblast,"<sup>34</sup> "prorubricyte"<sup>34</sup>) is a round or oval cell of moderate to large size (14 to 19  $\mu$ m diameter). It possesses a relatively large nucleus and a rim of basophilic cytoplasm (Plate IV, B, Plate IX, A). The nucleus of the youngest cells in this group may differ but little from that of the myeloblast. Nucleoli are present and may be prominent. There is a very thin or delicate nuclear membrane. At this stage no hemoglobin can be made out in the cell, consequently its classification as a member of the red cell series is difficult. As compared with that of myeloblasts and lymphoblasts, the cytoplasm has a tendency to be more homogeneous and condensed and may appear granular. A small, pale area may be found in the cytoplasm, possibly corresponding to the Golgi apparatus.<sup>37</sup> The nuclear chromatin is somewhat more coarse than that in myeloblasts or lymphoblasts. In supravital stained preparations a number of rod-shaped mitochondria are seen in the cytoplasm.

The basophilic normoblast (basophilic

erythroblast of Ferrata, early erythroblast of Sabin, "basophilic rubricyte"<sup>34</sup>) is similar to the pronormoblast except that the nucleoli are no longer visible and the cell usually is somewhat smaller (12 to 17  $\mu$ m diameter) (Fig. 3-2, 3a; Plate IV, B; Plate IX, B). The chromatin has the appearance of coarse, granular material, and there is thus little resemblance to the myeloblast. The nuclear structure may assume a wheel-spoke arrangement ("Radkern"), and there tends to be a sharp contrast between chromatin and parachromatin. The cytoplasm is deeply basophilic, even more so than in the pronormoblast. This color is a manifestation of the presence of ribonucleic acid (RNA). The color changes during subsequent stages reflect the appearance of acidophilic hemoglobin and the disappearance of RNA.

The first faint blush of hemoglobin, as indicated by one or more pink areas near the nucleus in dry fixed preparations, introduces the next stage which is called the polychromatophilic normoblast (late erythroblast of Sabin, polychromatophilic rubricyte<sup>34</sup>) (Fig. 3-2, 3b; Plate IV, F; Plate IX, C, D). Increasing condensation of nuclear chromatin is observed during this stage. Irregular lumps of chromatin are formed, which may stain very deeply. Nucleoli are not visible. The nucleus is smaller (7 to 9  $\mu$ m) as is the cell as a whole (12 to 15  $\mu$ m). With supravital stains, the maximum number of mitochondria will be found in the early phases of this stage, but, as hemoglobin becomes more plentiful, mitochondria decrease in number.

When the cytoplasm possesses almost its full complement of hemoglobin, the cell is termed an orthochromatic (acidophilic) normoblast (Fig. 3-2, 3c; Plate IX, E), a designation meant to imply that the cytoplasmic hue is similar to that of mature erythrocytes. Strictly speaking, normoblasts are rarely fully orthochromatic, but this term is convenient in distinguishing the more acidophilic from the distinctly polychromatophilic stage. The orthochromatic normoblast is the smallest of the nucleated erythrocyte precursors (8 to 12  $\mu$ m in diameter).

In this final stage, the nucleus undergoes

# PLATE IV

*Megaloblasts and normoblasts, from bone marrow (Wright's stain,  $\times 1220$ ) A, C, E and G are from the bone marrow of patients with pernicious anemia in relapse and show various stages in the development of these cells. In the top row, a basophilic megaloblast (A) is contrasted with a basophilic pronormoblast (B) from a patient with idiopathic refractory anemia. The basophilic and polychromatic normoblasts in D and F are contrasted with megaloblasts (C, E, and G) at approximately corresponding stages of development.*

Fig. 3-2 Nucleated red cells from the rat yolk sac (1a b c) bone marrow of a patient with pernicious anemia (2a b c) and embryonic rabbit liver (3a b, c). Series 3 represents basophilic (a) polychromatophilic (b) and orthochromatic (c) normoblasts. Series 2 shows megaloblasts in the same order. Series 1 illustrates the appearance of the primitive erythroblasts found in the yolk sac. Dry imprint May-Grünwald-Giemsa stain prepared by Dr. A. Kirschbaum  $\times 1400$  (From Jones,<sup>21</sup> in *Downton's Handbook of Hematology*, courtesy of the author and Paul B. Hoeber, Inc.)

pyknotic degeneration, the chromatin becomes greatly condensed, and the nucleus shrinks. The nucleus may appear to be an almost homogeneous mass. It may assume various bizarre forms such as buds, rosettes, clover leaves, or double spheres, or only a faint ring may remain. That the changing pattern of the nuclear chromatin is not an artifact produced by fixation has been shown by studies with the electron microscope.<sup>29</sup> Distortions of this process have been described.<sup>16</sup> Finally the nucleus is lost.<sup>5</sup>

The proportions of various nucleated red cells in normal bone marrow are given in Chapter 2 (page 62).

### Reticulocytes

After the nucleus has been lost, certain cytoplasmic organelles, such as ribosomes, mitochondria, and the Golgi complex, persist for a short time. Methyl alcohol or similar fixative agents used in staining cause a uniform precipitation of the ribosomal RNA, a basophilic substance, and the intensity of the basophilic staining is roughly proportional to the amount of RNA present. After staining, such cells may appear uniformly blue or gray (*diffuse basophilia*), or various basophilic shades may be intermingled with pink-staining portions (*polychromatophilia* or

*polychromasia*). The effects of overstaining, which affects all the red corpuscles in the smear, must be distinguished from true basophilia which is found only in a small proportion of the cells.

*Punctate basophilia or basophilic stippling* is the term applied when there are bluish or bluish-black granules in red corpuscles stained by one of the Romanowsky methods. The granules may be fine or coarse, are usually uniform and round but may be angular, and have been seen in the unstained condition as well as by darkfield illumination.<sup>26</sup> Staining by special supravital methods demonstrates a third type of basophilia, the "substantia granulo-filamentosa" (Cesaris-Demel). These "skein cells" were first observed by Ehrlich and their significance was appreciated by Theobald Smith, but only much later did *reticulocytes*, as they came to be called, assume a position of importance in hematologic technology.

The *relationship of diffuse basophilia, stippling, and reticulocytes* has long intrigued hematologists and a close but imperfect parallelism between these three morphologic entities has been recognized. It can now be accepted that they are the result of different manipulations of the red cell in preparation for microscopy. Rapid fixation or strong fixing agents produce a high proportion of polychromatophilic cells and few stippled cells, whereas prolonged staining has the opposite effect.<sup>7</sup> That the basophilic material which is seen as "stippling" is composed wholly or in part of RNA is indicated by ultraviolet light absorption and by the fact that it disappears on treatment with ribonuclease.<sup>9</sup> By electron microscopy it can be seen in the form of ribosomal aggregates.<sup>20</sup> Non-heme iron and mitochondria may be associated with the aggregates, but can be differentiated.

In contrast to stippling, the "reticulum" of reticulocytes cannot be seen, even by dark-ground illumination or by phase contrast microscopy unless stained. However, examination by ultraviolet light with the wavelength that is absorbed by nucleic acids<sup>2</sup> and observation of the effect of ribonuclease on

the basophilic material<sup>9</sup> indicate that the reticulum, like the stippled material, also is composed in whole or in part of RNA. The precipitation of ribosomes by cresyl blue produces the reticular network visible by light microscopy.

In reticulocytes, the reticulum may appear as a narrow band traversing the cell, it may be evenly distributed throughout the cell, or it may be so densely packed as to give the appearance of a nucleus. Generally speaking, the amount of reticulum in reticulocytes decreases as the cells mature, and in "old" reticulocytes only a few granules or scattered threads may be found.<sup>17</sup> The shape and density of the network also depend, however, on a number of physical factors. Thus, the stronger the concentration of the dye, the larger and less broken up is the reticulum.<sup>7</sup> Drying of the film tends to produce a fine reticulum. Heating tends to destroy the reticulum, only rods and granules being demonstrable. A change in the pH of the staining mixture towards the acid side results in a finely granular reticulum, whereas treatment with dilute alkali produces a stippled form.<sup>28</sup> Substances such as glucose and sodium salts inhibit the staining of reticulocytes.<sup>18</sup> Crenation of red corpuscles is said to obstruct the passage of dye into the cells.<sup>7</sup>

Reticulocytes are larger than fully matured red corpuscles, perhaps 20% greater in volume.<sup>23</sup>

### *Electron Microscopic Findings<sup>22,29</sup>* (Figs. 3-3, 3-4 & 3-5)

Within hours after differentiation of the stem cell into the pronormoblast, *ferritin* can be found in the cytoplasm. On electron microscopy, this large, iron-containing protein has the characteristic appearance of a tetrad, making positive identification possible. Ferritin may appear as isolated molecules within the cytoplasm, or it may be found in pinocytic vesicles or in larger structures (often surrounded by a membrane) which have been called *siderosomes*. The sources and metabolic fate of ferritin will be discussed in Chapter 4 (page 162). Its morphologic importance is

Fig. 3-3. Schematic diagram of the ultrastructure of the normoblast as visualized by electron microscopy (Courtesy of Dr. Marcel Bessis)

that it constitutes an important criterion in identifying a given cell as an erythrocyte precursor.

The cytoplasm of erythrocyte precursors contains *ribosomes*, but for the most part these remain free within the cytoplasm rather than being part of a well-defined endoplasmic reticulum. In cells which are actively synthesizing hemoglobin, the ribosomes are found in units known as polyribosomes; these consist of two to eight individual ribosomes joined together by a strand of messenger RNA. Ribosomes reach their maximum number during the basophilic normoblast stage and gradually disappear as the cell matures. They persist for several days following denudation and are the principal constituent of the "reticulum" demonstrable in reticulocytes by supravital staining procedures (page 31).

In erythroid cells, *mitochondria* are round or oval in shape, and the cristae are less distinct than in other cell lines. They are most numerous in the earlier stages of maturation, but some are found in reticulocytes as well

and may aggregate with ribosomes in the "reticulum."

Many small *vesicles* about 50 nm in diameter are seen throughout the cytoplasm. They have a single membrane with an indistinct inner layer, and they sometimes contain ferritin particles.<sup>37</sup> These vesicles are thought to arise by a process termed "pinocytosis" or "rhopheocytosis" (Fig. 3-3), whereby macromolecular substances are brought into the cell. The vesicle is formed from an invagination of the cell membrane, followed by closure to form a vacuole which later separates from the membrane.

Other cytoplasmic structures found in the young normoblast include a Golgi apparatus and occasional, randomly oriented *microtubules*. The latter are of unknown function, but may represent remnants of the marginal band, a cytoskeletal structure characteristic of erythrocytes of lower species.<sup>13</sup> Alternatively, they may be remnants of mitotic spindles.<sup>37</sup>

The *nucleus* of the pronormoblast is somewhat irregular in shape in contrast to the

**Fig 3-4** Basophilic normoblast viewed by electron microscopy. Compare with diagram of the ultrastructure of the erythroblast shown in Figure 3-3. Mitochondria, microtubules, fibrils, and polyribosomes are easily seen. (Courtesy of Dr. Marcel Bessis.)

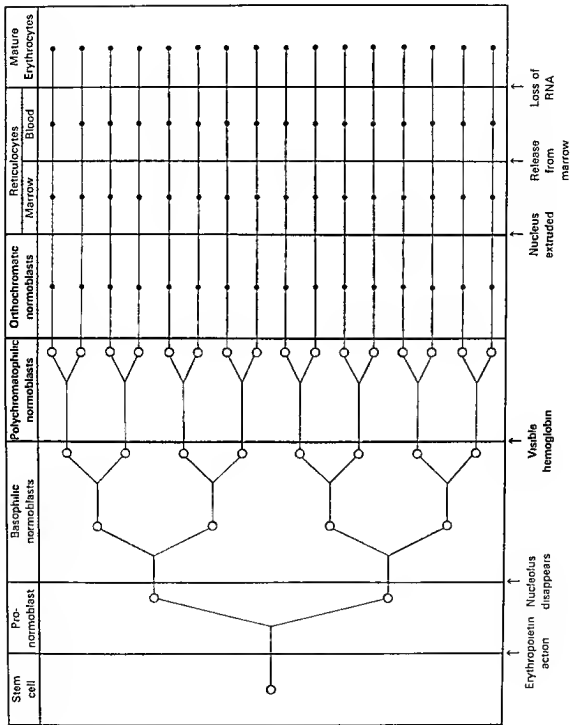

Fig. 3-5 A reticulocyte as viewed by electron microscopy is shown in the lower portion of this figure. Polynibosomes, mitochondria, and a large ferritin mass are easily seen. The irregular margin of the cell reflects the cellular movement that takes place at this stage.

A nucleus expelled from a normoblast is shown above the reticulocyte. A crown of cellular cytoplasm surrounds it. (Courtesy of Dr. Marcel Bessis.)

more nearly spherical form found in more mature cells. The nucleolus is large and well developed in the pronormoblast, but with increasing maturity it diminishes rapidly in both size and activity. In the basophilic normoblast, only traces of nucleolar material can be detected. Many nuclear pores connect

the nucleoplasm with the cytoplasm, and these pores decrease in number as the cell matures.<sup>57</sup> The nuclear chromatin appears homogeneous in pronormoblasts, but condensation (formation of heterochromatin) begins early in the basophilic normoblast stage. Condensation appears to begin near the

nuclear membrane and to extend thereafter toward the center in irregular radial lines. Finally, in the orthochromatic normoblast, the nucleus is nearly all heterochromatin.

### Proliferation and Maturation of the Erythron

Within the erythron, cellular maturation and proliferation proceed simultaneously. All morphologically identifiable erythrocyte precursors are destined to mature; thus, they are incapable of self-maintenance. Maintenance of the erythron at a given size and its expansion on demand are functions of the stem cell compartment (Chapter 2), and are under hormonal control (Chapter 4, page 180).

Details of the proliferation scheme within the erythron are incompletely understood since they must be based on certain assumptions. For example, the calculation of the time a cell spends in a given morphologic stage (the compartment transit time or CTT) depends on whether the products of mitosis are assumed to be recognizably more mature than the mother cell (ie, "heteromorphogenic" division) or whether the daughter cells are indistinguishable from the mother cell ("homomorphogenic" division).<sup>24</sup> Depending on which of these two types of division is assumed, the CTT for basophilic normoblasts may be as short as 12.4 hours or as long as 95 hours and for polychromatophilic normoblasts, 8.8 to 37.5 hours. The CTT for pronormoblasts is about 30 hours and for orthochromic normoblasts, 19 hours.<sup>24</sup> Thus, it takes from 70 to 180 hours for a pronormoblast to develop into a marrow reticulocyte. An additional two to three days elapse before release from marrow to blood.<sup>10</sup>

Probably three to five cell divisions occur during the maturation of erythroid precursors.<sup>31</sup> Thus, 8 to 32 mature red cells are derived from each pronormoblast. For illustrative purposes, the scheme outlined in

Figure 3-6 assumes that four divisions occur, two of these during the basophilic normoblast phase and one each at the end of the pronormoblast and polychromatophilic normoblast stages, respectively. Orthochromatic normoblasts cannot synthesize DNA, and, therefore, cannot divide.

Two events may decrease the theoretic yield of cells. One of these is the death of the cell prior to or shortly after its release from marrow ("*ineffective erythropoiesis*") (Chapter 13, page 550). The second is a skipped cell division, a phenomenon that results in a large, hemoglobin-poor cell (Chapter 14, page 567). Both of these events occur to only a limited extent in normal subjects, but may be greatly increased under pathologic circumstances.

Presumably, the differentiation of stem cell to pronormoblast is accomplished by the induction of certain genes, especially those necessary for hemoglobin synthesis, and by repression of others not required for erythrocyte function. The pronormoblast stage is dominated by the process of RNA synthesis, as is implied by the presence of the large and active nucleolus. Three species of RNA are formed—ribosomal, transfer (tRNA), and messenger (mRNA)—probably in relative proportions of approximately 80:15:5 respectively.<sup>12</sup> The synthesis of RNA declines as the cell matures (Fig. 3-7) and probably ceases toward the end of the basophilic stage.<sup>11</sup>

Proteins synthesized during the pronormoblast phase are mainly non-hemoglobin proteins. The first traces of hemoglobin may be detected in the basophilic normoblast stage, but hemoglobin is not apparent on light microscopy until the polychromatophilic stage. Here, the rate of hemoglobin synthesis reaches a maximum. Hemoglobin synthesis continues through the orthochromic stage and persists in the reticulocyte after denucleation. Mature red cells, being devoid of ribo-

Fig 3-6. Proliferation within the erythron as related to morphologic stage. Three to five divisions occur (four are shown here) between the pronormoblast stage and the reticulocyte. Thus there is a yield of 8 to 32 cells per pronormoblast. However, no cell at the orthochromatic stage or older is capable of mitosis. The principal events associated with the morphologic stages are indicated on the lower margin.

**Fig 3-7** Erythroid maturation alterations in cell size, rates of DNA and RNA synthesis, enzymes involved in heme synthesis, and hemoglobin concentration. Substances listed in the left hand column are represented by corresponding solid black lines. Unless specified, graphs represent relative values. ALA refers to  $\delta$ -aminolevulinic acid. PROTO refers to protoporphyrin. It will be noted that considerable protein synthesis takes place during the earliest phase. Following this the nucleus disappears but mitochondria remain. As the concentration of DNA decreases and the concentration of RNA starts to fall, hemoglobin begins to appear, increasing rapidly in amount. (From Granick and Levere,<sup>12</sup> courtesy of the authors and Grune & Stratton.)

somes, are unable to synthesize hemoglobin.

As previously noted, morphologic evidence of nuclear degeneration (heterochromatin formation) can be seen as early as the basophilic normoblast stage. By the orthochromatic stage, the nucleus is completely inactive, unable to synthesize either DNA or RNA. The factors leading to cessation of nuclear activity are not fully understood, but there is evidence that they may be related to intracellular hemoglobin concentration.<sup>35</sup>

Hemoglobin is found within the nucleus, possibly gaining entrance through pores in the nuclear membrane.<sup>27,35,39</sup> After reaching a critical concentration (possibly 20 g/dl)<sup>40</sup> nuclear hemoglobin may react with nucleohistones thereby bringing about chromosomal inactivation and nuclear condensation. According to this hypothesis, the number of cell divisions and the ultimate erythrocyte size are related to the rate of hemoglobin synthesis. For example, microcytic cells are

produced in iron deficiency because it takes longer to reach the critical hemoglobin concentration and the generation time is unaffected; hence, more cell divisions occur before nuclear inactivation, and the resulting cell is small. In contrast, the macrocytes observed when erythropoiesis is stimulated may be conceived as the end result of an erythropoietin-induced acceleration of hemoglobin synthesis which in turn leads to an earlier onset of nuclear degeneration and a reduced number of cell divisions. Also consistent with this hypothesis is the observation that the mean corpuscular hemoglobin concentration remains relatively constant in a variety of mammalian species, even though erythrocyte size varies greatly<sup>10</sup> (Fig. 3-18).

After the nucleus degenerates, it is extruded from the cell.<sup>1</sup> This process, which has been observed in living normoblasts by phase contrast microscopy,<sup>30</sup> is completed in 5 to 60 minutes. During the extrusion process, mitochondria and cytoplasmic vesicles accumulate near the nuclear border.<sup>33,37</sup> The role of these structures in nuclear extrusion is not entirely clear, but supravital staining with Janus green B, a mitochondrial toxin, inhibits denucleation.<sup>1</sup> The extruded nucleus carries with it a rim of cytoplasm (Fig. 3-5), including ribosomes, hemoglobin, and occasional mitochondria. Within the marrow, denucleation appears to occur as the erythroblast traverses the endothelial cell that forms the sinus wall.<sup>38</sup> The normoblast cytoplasm and small organelles (ribosomes and mitochondria) squeeze through endothelial, cytoplasmic pores 1 to 4  $\mu\text{m}$  in diameter, but the more rigid nucleus cannot conform to this pore size. The nucleus thus becomes caught and "pitted" from the cell. Soon after denucleation, the nucleus is engulfed by a macrophage.

Following denucleation, the cell remains within the marrow as a reticulocyte for several days. Factors controlling release into the circulation have been discussed in Chapter 2 (page 60).

After release, the reticulocyte may be sequestered for one to two days in the spleen.<sup>31</sup> Here, additional maturation may occur, and

the composition of membrane lipids may be altered.<sup>32</sup>

Reticulocytes are more adhesive than adult corpuscles and move about in currents at a much slower rate than do mature cells.<sup>7</sup> This adhesive property, like that described for more primitive cells,<sup>19</sup> may account for their tendency to remain within the bone marrow under normal conditions (page 60). They appear to have a coating of globulin,<sup>36</sup> at least part of which is transferrin.<sup>20</sup> Their specific gravity is lower than that of adult corpuscles<sup>22</sup> and they tend to collect in the upper portions of suspensions of corpuscles. They vary in their resistance to hypotonic solutions.<sup>6</sup> They have metabolic pathways that are lacking in mature red cells, including an intact tricarboxylic acid cycle.<sup>11</sup>

## The Mature Erythrocyte

The mature mammalian erythrocyte is one of the most highly specialized of cells. It is devoid of the usual cytoplasmic organelles such as nucleus, mitochondria, or ribosomes. Thus, it consists of little more than a membrane surrounding a solution of protein and electrolytes. More than 95% of the protein is hemoglobin. The remaining protein includes those enzymes required for energy production and for the maintenance of hemoglobin in a functional, reduced state.

### Shape and Dimensions

The resting shape of the normal human erythrocyte is that of a flattened, bilaterally indented structure, a shape often referred to as a "biconcave disc" (Fig. 3-8). In fixed, stained blood smears, only the flattened surfaces are observed; hence, the appearance is circular, with an area of central pallor corresponding to the indented areas (Fig. 1-7, page 27).

The normal mean diameter of red cells, measured after drying and staining, is variously given as 7.2 to 7.9  $\mu\text{m}$ .<sup>61,93,117</sup> Means as low as 6.9<sup>91</sup> and 6.5  $\mu\text{m}$ <sup>61</sup> have been reported in normal persons. In individual preparations, cells as small as 4.75  $\mu\text{m}$  and as large as 9.5  $\mu\text{m}$  may be found,<sup>91</sup> but generally the

Fig 3 8 The normal mature erythrocyte as visualized by the scanning electron microscope ( $\times 9800$ ) (Courtesy of Dr Wallace N Jensen)

greatest variation in the diameters of the cells is  $3.5\text{ }\mu\text{m}$ .<sup>61</sup> Diameters measured in wet films are  $0.8$  to  $1.4\text{ }\mu\text{m}$  greater than those just mentioned.<sup>51,115</sup> The normal mean thickness of red corpuscles has been reported to be  $2.14\text{ }\mu\text{m}$ ,<sup>94</sup>  $2.05\text{ }\mu\text{m}$ , or  $1.84\text{ }\mu\text{m}$ , and even  $1.64\text{ }\mu\text{m}$ .<sup>115,117</sup>

The mean volume of the normal human erythrocyte is about  $87\text{ fl}$  (range  $80$  to  $96$ )<sup>52,70,79,81,105,118</sup> as calculated from the ratio of the volume of packed red cells and the erythrocyte count (see page 116). Somewhat greater values, approximately  $108\text{ fl}$ , have been suggested from measurements

made on microscopy of hanging-drop preparations.<sup>54</sup>

The surface area of the erythrocyte<sup>54</sup> is about  $140\text{ }\mu\text{m}^2$ , considerably greater than that expected if volume were distributed in a sphere.

From cinematomicrographic observation of red cells within blood vessels, it is clear that their shape can be easily altered to facilitate passage through small vessels.<sup>104</sup> In such studies, the plane of the biconcave disc is found to be oriented in the direction of flow. The leading edge becomes pointed and the following edge blunted (Fig. 3-9); thus, the shape becomes similar, to that of a parachute or torpedo viewed from the side. When deformed in this way, the erythrocyte can pass through a vessel of about  $4\text{ }\mu\text{m}$  in maximum diameter. Because of the disc shape, alterations can be accomplished with relatively little change in surface area. If the erythrocyte were spherical in shape, considerable stretching of its membrane would be required to enable it to conform to small vessels.

The forces that cause the erythrocyte to maintain its resting, biconcave form are only partially understood. It has been suggested that the cell simply assumes the shape that utilizes the minimum energy of bending (least total curvature).<sup>63</sup> Others have calculated that the interplay of three distinct forces is required to maintain shape: a hydrostatic pressure difference across the membrane, a constant tension within the membrane, and

Fig 3 9. Human erythrocytes flowing through a vessel about  $7\text{ }\mu\text{m}$  in diameter. Direction of flow is indicated by the arrow (From Skalak and Branemark,<sup>104</sup> courtesy of the authors and Science)

a third force acting to indent the two sides.<sup>82</sup> It is possible that this apparent third force is the consequence of a variation in surface tension resulting from the peculiar distribution of membrane cholesterol.<sup>87</sup> However, observations with polarized light have indicated that there is an internal organization of molecules that contributes to shape.<sup>103</sup> One simple proposed model compares the erythrocyte to a partially deflated tennis ball, the equatorial region of which has been strengthened by an increased wall thickness or by fibrillar structures.<sup>92</sup> In such a model, the biconcave shape is stable.

### The Erythrocyte Membrane

The erythrocyte membrane is a dynamic component of the cell. It has the property of selective permeability, and it facilitates the

passage of cations against an ionic gradient. It also serves as the site of attachment for certain enzymes. By these means, it maintains the intracellular fluid and electrolyte environment within relatively narrow limits.

### Models of Membrane Structure

It is not possible to characterize the membrane completely in molecular terms. A variety of models of membrane structure have been proposed. These fall generally into two main categories: those based on the unit membrane, or lipid bilayer model originally proposed by Danielli<sup>88,89</sup> and modified by Robertson;<sup>90,97</sup> and those based on structural or functional subunits, a concept developed by Green and coworkers from studies of mitochondrial membranes.<sup>69</sup> The central feature of lipid bilayer models is an orderly arrangement of phospholipids into a sheet two molecules thick (Fig. 3-10A). The molecules are so oriented that the nonpolar groups of the two layers are directed toward one another, forming lipid-lipid interactions. The polar groups are directed outward and interact with protein on both the extracellular and intracellular surfaces.

It seems clear that this relatively homogeneous structure must be interrupted at some

Fig 3-10. Models of membrane structure. A, Lipid bilayer membrane model. 1 Protein polypeptide chain, 2 mucopolysaccharide, 3 phospholipid, circles indicate the polar end. 4 cholesterol (From Fikrin and Wiley,<sup>84</sup> courtesy of the authors and Grune & Stratton.)

Fig 3-11. Ultrastructure of the erythrocyte membrane. A, Thin section, B, metal shadowed surface, C, freeze cleaved. Two surfaces are shown designated A and B, differing in the number of membrane-associated particles (MAP). D, Artist's conception of the surfaces exposed by freeze cleaving. (From Hoffman,<sup>74</sup> Robertson,<sup>77</sup> and Weinstein and McNutt<sup>114</sup> courtesy of the authors and American Journal of Medicine, Archive of Internal Medicine and Seminars in Hematology, respectively.)

points in order to provide for certain membrane functions. In these areas, the lipid bilayer may be replaced or modified to form a functionally specialized site. For example, it has been estimated that there may be 100 to 200 sites at which  $K^+$  transport occurs.<sup>73</sup> Such sites may occupy only a small proportion of the membrane area.<sup>106</sup>

Membrane models of the subunit type (Fig. 3-10B) are based on the assumed exis-

tence of one or a few classes of lipid-protein structural subunits, usually of macromolecular size. These are joined together to form the membrane, and may, in fact, be capable of self-assembly. Functional subunits are also proposed, consisting of all the elements necessary to carry out a given function.

Evidence for and against the two types of models has been summarized in several reviews.<sup>66,106,122</sup>

## Ultrastructure

In thin sections of erythrocyte membrane, fixed with either osmium tetroxide or potassium permanganate, three distinct layers are observed (Fig. 3-11). There are two electron-dense (osmophilic) layers approximately 2.5 nm (25Å) in thickness separated by an electron penetrable layer about 2.0 nm thick, for a total thickness of some 7.0 nm.<sup>50</sup> This appearance has often been cited in support of the lipid bilayer model, with the electron-dense areas representing either membrane protein layers or the polar ends of the phospholipids.<sup>97</sup> There is no agreement, however, on the molecular meaning of the three layers, since the reactions of osmium and permanganate with membrane components are not fully understood.

With air-dried, metal-shadowed red-cell membranes, features of the surface are made apparent.<sup>72</sup> In such preparations, plaques about 3.0 nm thick and 10 to 50 nm in diameter are observed, and these are distributed randomly over the surface (Fig. 3-11). These observations have been used to support the subunit model of membrane structure, with each of the plaques representing the morphologic equivalent of a lipid-protein subunit. However, a major criticism of such preparations is that it is not possible to distinguish structures that are part of the membrane from extraneous material on the membrane surface.

Still another technique used in electron microscopy of membranes is that of "freeze-cleaving."<sup>114</sup> Erythrocytes are frozen rapidly at  $-150^{\circ}\text{C}$  and cleaved with a razor blade. The cleavage plane follows pathways of least resistance, frequently exposing large areas of membrane. These surfaces are replicated with condensed carbon and platinum and the replicas are examined with the electron microscope. Two types of membrane surfaces are observed with this technique (Fig. 3-11). Both surfaces are characterized by the presence of particles approximately 10 nm in diameter. The two surfaces differ in that one has four to five times as many of these particles as the other (2600 to 3800/ $\mu\text{m}^2$  as com-

pared with 575 to 1400/ $\mu\text{m}^2$ ). Although interpretation of these observations remains controversial, the best evidence suggests that the cleavage plane splits the normal membrane into two halves (Fig. 3-11). If the lipid bilayer model is correct, the split may occur between the two lipid molecules; i.e., in the nonpolar region. Some of the observed particles can be shown to penetrate through the entire thickness of the membrane, suggesting that they may represent specialized functional sites.

## Chemical Composition of the Membrane

Much that is known about red cell membranes is derived from studies of the insoluble portion of the cell remaining after hemolysis. This material is called *stroma* (or, if the membrane remains intact after hemolysis, red cell "ghosts") and consists largely of components of the membrane.

It is difficult to prepare stroma completely free of hemoglobin. This observation led to the speculation that hemoglobin might be an integral part of the membrane. However, this hypothesis was doubted when it was found that labeled hemoglobin exchanged freely with stroma-bound hemoglobin.<sup>73</sup> Furthermore, with careful attention to pH and osmolarity, it has been possible to prepare stroma essentially free of hemoglobin.<sup>60,113</sup> About 230 to 300 mg of stroma can be extracted from 0.1 liter of erythrocytes. Such preparations contain 40 to 50% protein, 35 to 45% lipid, and 7 to 15% carbohydrate.<sup>51,60,121</sup> Earlier determinations reported a higher proportion of protein, probably because of a greater degree of hemoglobin contamination.

**LIPID COMPOSITION.** Of the three classes of membrane components the most detailed information available concerns lipids. Virtually all of the lipids in the mature erythrocyte are found in the membrane.<sup>60</sup> Qualitative and quantitative analyses have been performed in a number of laboratories and the data have been the subject of several reviews.<sup>55,107,111,112</sup> These results are summarized in Table 3-1. Values in children differ only slightly from those found in adults.<sup>88</sup>

Table 3-1. Lipids of the Normal Human Erythrocyte Membrane

Lipid	Molar Concentration <sup>101</sup>		Weight Concentration <sup>55</sup>	
	( $\mu$ mol/ $10^{10}$ cells)	% of total	(mg/ $10^{10}$ cells)	% of total
Neutral lipids				
Cholesterol	3.2		1.3 (1.1-1.4)*	
Free fatty acids	<0.1			
Total neutral lipid	3.2	43	1.3	29
Phospholipids				
Phosphatidylcholine (lecithin)	1.2		1.0	
Phosphatidylethanolamine (cephalin)	1.1		0.9	
Sphingomyelin	1.0		0.8	
Phosphatidylserine	0.6		0.4	
Lysolecithin	0.04		—	
Others	0.07		—	
Total phospholipids	4.0	54	3.1 (1.7-3.2)*	69
Glycolipids (globoside)	0.2	3	0.1	2
Total lipids	7.4	100	4.5 (3.9-5.2)*	100

\*Ranga<sup>111</sup> in parentheses

The neutral lipid of the erythrocyte consists almost entirely of free, non-esterified cholesterol.<sup>69</sup> Trace amounts of free fatty acids may also be found. The suggestion of the presence of cholesterol esters and triglycerides offered by earlier studies can probably be explained by the presence of contaminating traces of plasma lipoproteins.<sup>69</sup>

Most of the phospholipid of the erythrocyte membrane is accounted for by four classes of compounds: phosphatidylcholine (lecithin), phosphatidylethanolamine, sphingomyelin, and phosphatidylserine (Table 3-1). To each of these lipids are attached two fatty-acid side chains, except for sphingomyelin, which has but one. Trace amounts of other phospholipids containing only one fatty acid ("lysophospholipids"; eg lysolecithin) or in which a fatty acid has been replaced by a vinyl ether (plasmalogens) are found.

Of the fatty acids found in red cell phospholipids, about half are saturated and half are unsaturated (Table 3-2). These fatty acids

are not evenly distributed among the phospholipids. For example, lecithin contains most of the shorter-chained, saturated fatty acids, phosphatidylethanolamine is rich in unsaturated fatty acids; stearic acid predomi-

Table 3-2. Fatty Acids in Erythrocyte Phospholipids

Fatty Acid	Molecular Designation*	%
Saturated		
Palmitic	16:0	24.5
Stearic	18:0	19.0
Others		3.1
Total saturated		46.6
Unsaturated		
Oleic	18:1	16.4
Linoleic	18:2	11.2
Arachidonic	20:4	15.1
Others		10.3
Total unsaturated		53.0

From Ways and Hanahan,<sup>112</sup> courtesy of the authors and Journal of Lipid Research

nates in phosphatidyl serine; and fatty acids of chain length longer than 20 are found, especially in sphingomyelin.<sup>55</sup> The fatty acid composition of the membrane influences its rigidity; saturated fatty acids, being less fluid, lend stiffness to the membrane.

The glycolipids (or glycosphingolipids) make up a small fraction of the total lipids of the erythrocyte membrane, but are, nevertheless, of unique biologic and pathologic importance.<sup>107</sup> These glycolipids resemble sphingomyelin in that the lipid base is a unit known as *ceramide*, consisting of sphingosine and a long-chain fatty acid. To the base is attached a variable number of hexose molecules. The predominant erythrocyte glycolipid, *globoside* (GL-4), contains four hexose units:

Globoside appears to be a component only of plasma membranes as distinguished from the membranes of intracellular organelles, such as mitochondria. In this respect, it differs from cholesterol and the phospholipids, which are widely distributed. Globoside is particularly characteristic of the red cell membrane, but has also been isolated from leukocytes and the kidney and may be present in plasma membranes of still other cells.

Normal human red cells also contain ceramide glycolipids with 1 glucose (GL-1), 1 glucose and 1 galactose (GL-2), and 1 glucose and 2 galactose molecules (GL-3) attached. The relative proportions of these are as follows: GL-4, 69%; GL-3, 12%; GL-2, 14%; and GL-1, 5%.<sup>107</sup> In addition, there are trace amounts of fucose-containing ceramide glycolipids. These are of interest because they have antigenic activity corresponding to the A, B, H, and Lewis blood groups. They may not be the exclusive bearers of these antigens, however, since glycoproteins with similar hexose arrangements have similar antigenic properties (page 100).

**LIPID TURNOVER AND ACQUISITION.**<sup>101</sup> The mature erythrocyte is unable to synthesize lipids *de novo*; therefore, any lipid loss must

be compensated for by renewal from pathways of interchange with the plasma (Fig. 3-12). Quantitatively, the most important of these pathways are the transfer of cholesterol and lecithin (phosphatidyl choline) from plasma lipoproteins to red cells (pathways 1 and 3). The rates of transfer are functions of the relative plasma and red cell levels of these lipids and are indirectly affected by the activity of the cholesterol esterifying enzyme in plasma, lecithin-cholesterol acyltransferase (LCAT).<sup>68</sup> This enzyme catalyzes the reaction in which a fatty acid in the 2 position of lecithin is transferred to free cholesterol, forming cholesterol ester and lysolecithin (Fig. 3-12, reaction 1A). Neither of the LCAT reaction products can enter the membrane.

The activity of LCAT probably accounts for the observation that cholesterol is lost from the membrane when erythrocytes are incubated in normal, glucose-containing plasma.<sup>57</sup> The cholesterol loss is accompanied by a decrease in red cell surface area and a spheroidal change in red cell shape. These abnormalities are reversible when cells are infused *in vivo*. Conversely, in patients with congenital LCAT deficiency, membrane cholesterol and lecithin are increased and the red cells are target-shaped.<sup>91</sup>

The exchange of cholesterol and lecithin between red cells and plasma also is affected by the plasma bile-salt concentration.<sup>56</sup> If erythrocytes are incubated in normal plasma to which bile salts have been added, the cells acquire cholesterol, and this change is accompanied by an increase in surface area and the formation of target cells. Although the mechanism of bile-salt action is not fully understood, at least two properties appear important: bile salts inhibit the LCAT reaction and, in addition, they bring about a shift in the distribution of free cholesterol between plasma and cell.

Phospholipids also may be added to the membrane by three other reactions. An albumin-bound lysophospholipid may be transferred to the membrane (Fig. 3-12, pathway 4) and acylated (reactions 5a and 6a) to form a complete phospholipid.<sup>101</sup> Of lesser quantitative importance is the transfer

(From Shohet,<sup>101</sup> courtesy of the author and New England Journal of Medicine.)

and conjugation of two lysophospholipid molecules to yield a phospholipid (reaction 5b) and glycyl-phosphorylcholine (GPC), which returns to the plasma.<sup>108</sup> Finally, some phosphatidyl ethanolamine (PE) is produced by transacylation of a fatty acid from lecithin to lyso-PE (reaction 6b). A congenital defect in the last reaction results in the formation of cells that possess increased membrane lecithin and decreased membrane PE. These changes are associated with the clinical picture of non-spherocytic hemolytic anemia<sup>102</sup> (Chapter 21).

The fatty acid composition, but not the

major relative proportions of the phospholipid classes, may be altered by dietary means.<sup>65</sup> With low-fat diets, linoleic acid decreases. With diets high in linoleic acid, red cell linoleic acid increases. These changes occur relatively slowly, over about a four- to six-week period.

Relatively little is known about the pathways of renewal of glycolipids. They appear to be synthesized in the bone marrow and incorporated into the membrane prior to release of the mature red cell.<sup>107</sup> It is possible that they remain with the cell throughout its life span. The enzymatic degradation of gly-

colipids occurs in macrophages by sequential cleavage of the hexose units. These reactions, and diseases which affect them, are discussed in Chapter 42.

**PROTEINS.**<sup>71</sup> The membrane proteins are not as well characterized as the lipids. Study of these proteins has been limited by the difficulty of extracting them from lipids and solubilizing them without destructive techniques. In early studies, the name "*elimum*" was applied to the insoluble membrane residue remaining after alkaline extraction and removal of lipids with ether.<sup>86</sup> It is now recognized that this material is a crude mixture of proteins, many of which are denatured.

Complete solubilization of membrane proteins has been accomplished by successive extraction with a chelating agent (EDTA), 0.8 M sodium chloride, ethanol-ether, and detergents (3% sodium dodecyl sulfate).<sup>98</sup> The detergent-soluble material has been further fractionated by gel-filtration. With these methods, seven to nine fractions of membrane proteins can be defined, and further heterogeneity can be detected by amino-acid end-group analysis in some of the fractions. These observations indicate that there are a minimum of 12 proteins (or polypeptide chains) in the membrane, and there may be many more than this minimum figure. Very sensitive techniques, such as electrophoresis of protein subunits in sodium dodecyl sulfate-polyacrylamide gel, demonstrate 35 to 40 components, some of which make up as little as 0.15% of the total.<sup>90</sup> As yet, little is known about the relation of these protein fractions to the structure or function of the membrane. However, two proteins have been more fully characterized, and appear to have special physiologic or pathologic significance.

The protein that becomes soluble in the presence of EDTA and other chelating agents has been designated "spectrin" because of its origin from red cell "ghosts."<sup>83</sup> Accounting for about 20% of stromal protein, spectrin contains no carbohydrate or lipid groups and appears homogeneous by electrophoresis, ultracentrifugation, and immunodiffusion. Amino acid analysis shows it to be particu-

larly rich in glutamic acid and to contain cysteine. The monomer appears to have a molecular weight of about 140,000, but polymers of varying size will form, depending on pH, concentration, and the nature of the buffer. Of particular interest is the tendency of spectrin to form insoluble filaments or fibers in the presence of divalent cations, especially calcium. Studies with electron microscopy of membranes before and after spectrin extraction suggest that the protein is located on the inner surface of the erythrocyte membrane.

The physiologic importance of spectrin is suggested by observations indicating deficiency or malfunction of a spectrin-like protein in hereditary spherocytosis (HS)<sup>70</sup> (Chapter 21). Extracts of membrane protein from patients with HS fail to precipitate or form fibers to the same degree as do normal extracts when exposed to divalent cations or vinblastine. Since the membrane in HS is excessively permeable, spectrin may be essential to the permeability barrier that characterizes the normal membrane.

Another well-studied membrane protein is the principal glycoprotein (or closely related family of glycoproteins) of erythrocyte stroma.<sup>84,119</sup> This protein, for which the name "erythrocyte glycoporphin" has been suggested,<sup>81</sup> accounts for about 10% of membrane protein. Glycophorin is found in one of the detergent-soluble fractions of membrane protein,<sup>98</sup> and may also be isolated by other methods, including extraction with lithium di-iodosalicylate<sup>84</sup> or with hot, aqueous phenol solutions, or by chromatography on Sephadex G-200 with 33% pyridine as eluant. In detergent solutions a molecular weight of about 55,000 is observed, but aggregates with molecular weights as great as 500,000 may occur. About 60% of the molecule is carbohydrate, accounting for most of the sialic acid of the membrane and about half of the hexose and hexoseamine as well as small amounts of mannose and fucose.

The membrane glycoprotein is found on the external surface of the cell. It is likely that the lipophilic, C-terminal end is attached to membrane lipids, and the more soluble,

carbohydrate-containing N-terminal end projects into the erythrocyte environment. The glycoprotein accounts for the characteristic negative charge of the red cell, which may act to prevent excessive erythrocyte agglutination. Another feature of this protein is that it carries the A, B, M, and N specific blood group antigens as well as "receptors" for influenza viruses, phytohemagglutinin, and wheat-germ agglutinin.

Other membrane proteins include certain enzymes that seem to be firmly attached to the erythrocyte membrane. These include glyceraldehyde-3-phosphate dehydrogenase,<sup>64,108</sup> aldolase,<sup>64</sup> 3-phosphoglycerate kinase,<sup>61</sup> adenylate kinase,<sup>61</sup> cyclic AMP-dependent protein kinase,<sup>109</sup> ATPase (page 101), cholinesterase,<sup>216</sup> and a thyroid hormone deiodinating enzyme.<sup>93</sup>

### Membrane Transport Functions

In general, the membrane acts as a partial barrier to penetration of all solutes. In the case of nonpolar substances, the rate of diffusion through the membrane usually is proportional to their solubility in organic solvents. Polar solutes apparently cross the membrane at specialized sites or pores.

One exception to the above generalization regarding nonpolar solutes exists in relation to the monosaccharides.<sup>85</sup> These easily cross the membrane barrier, whereas the more lipid-soluble disaccharides do not. Of the common hexoses, glucose is transported most rapidly, followed by mannose, galactose, xylose, arabinose, and fructose. Highly specific binding sites for D-glucose can be demonstrated on the red cell membrane.<sup>77</sup> In contrast to certain other tissues, the erythrocyte does not require insulin for penetration of glucose, nor is there any effect of thyroid or pituitary hormones. Glucose transport does not occur against a gradient, nor does it require energy. On the other hand, simple diffusion cannot explain the speed nor the kinetic pattern of uptake.<sup>85</sup> The conventional explanation for this type of facilitated diffusion is that monosaccharides combine with a membrane constituent, usually termed a "carrier,"

which then becomes reoriented toward the opposite side of the membrane and discharges its glucose into the cell. However, certain experimental observations are not easily explained by the carrier model, and non-carrier models currently are under study.<sup>80</sup>

Of the important polar substances, water and most anions, especially chloride and bicarbonate, diffuse freely and passively across the membrane. In contrast, the major monovalent cations, sodium and potassium, require an energy-dependent transport mechanism. This important process maintains the internal osmotic environment and preserves the normal gradients between plasma and intracellular concentrations of sodium and potassium.

Within the human erythrocyte, potassium is the predominant cation and sodium is a relatively minor constituent, whereas the relationship is reversed in plasma (Fig. 3-13). Unlike nerve and muscle cells, erythrocytes have no known function that requires maintenance of this cation relationship, in fact, some species, eg, dogs and cats, have an intracellular cation environment more nearly like that of plasma. However, the mechanism that maintains the electrolyte relationship also regulates the intracellular volume. If active cation transport is paralyzed, the cells accumulate sodium and water until a critical volume is reached, usually about 1.5 times normal, and then hemolysis ensues with discharge of cellular constituents into the surrounding space.

The steady-state cation concentrations within the erythrocyte are the result of an equilibrium between passive diffusion ("leak") and active transport ("pump").<sup>110</sup> In sodium, the direction of "leak" is inward and the direction of "pump" is outward; in contrast, potassium leaks out and is pumped in.

From *in vitro* studies it was proposed that three sodium pumps exist in the red cell (Table 3-3).<sup>74</sup> Two of these, designated Ia and Ib, are similar in that they require adenosine triphosphate (ATP) and are inhibited by cardiac glycosides such as ouabain. They differ from one another in that Ia requires potassium in the external medium and Ib requires sodium. Pump II is not inhibited by ouabain,

Fig 3-13 The intracellular electrolyte composition of the erythrocyte as compared with serum (From Guest<sup>70a</sup> courtesy of the author and American Journal of Diseases of Children)

but is inhibited by ethacrynic acid. The immediate energy source for pump II is unknown; it is not ATP, but glucose metabolism is required for its production. Others have presented evidence that "pump II" represents exchange diffusion, ie, a bidirectional flux that achieves no net sodium transport and, therefore, is not a "pump."<sup>63</sup> In any event, the most important pump is pump Ia, which exchanges sodium for potassium. The stoichiometry of the process is such that, for each molecule of ATP converted to ADP, three sodium ions are pumped out and two potassium ions enter.<sup>67</sup> One anion, usually chloride, leaves the cell passively to maintain elec-

trical neutrality. Ouabain-sensitive potassium exchange (K for K) has also been described in erythrocytes.<sup>100</sup>

Active cation transport appears to depend on a membrane-associated enzyme, adenosine triphosphatase (ATPase).<sup>62,78</sup> The enzyme may, in fact, be identical with the pump itself. It is this enzyme system that is inhibited by cardiac glycosides, and studies with these inhibitors suggest that there is a maximum of 250 sites on each red cell at which ATPase-dependent cation transport occurs. ATPase also is inhibited severely by low temperatures, accounting for the cellular potassium loss occurring during cold storage of blood.<sup>120</sup> The ATPase reaction may be divided into two essential steps: sodium- and magnesium-dependent phosphorylation, during which ATP is converted to ADP, and a potassium-dependent phosphatase reaction. Whether both are catalyzed by a single enzyme, or whether a structurally associated, double enzyme system is involved is not known. The reaction appears to require an intermediate, which is phosphorylated at the sodium-dependent step. The intermediate has not been fully characterized, and may be the enzyme itself; however, phosphatidylserine is required for optimal ATPase activity<sup>178</sup> and may be part of a cation carrier lipoprotein

that is powered by the reaction. The molecular weight of ATPase has been estimated at 300,000 to 400,000.<sup>62</sup>

### Glucose Metabolism

Although the mature red cell contains the enzymes required for glycogen metabolism, the balance between synthesis and utilization is such that no significant amount of glycogen accumulates within the cell.<sup>200</sup> Consequently, for its continued metabolism the erythrocyte must have constant access to glucose. As previously discussed (page 100), glucose enters the cell by a process of "facilitated transport," perhaps utilizing a carrier mechanism. There is no requirement for insulin or other hormones.

Lacking mitochondria, erythrocytes must depend on two much less efficient pathways for production of high-energy compounds. One of these is anaerobic glycolysis (Embden-Myerhof pathway), whereby glucose is broken down through a series of phosphorylated intermediates to lactate (Fig. 3-14, reactions 1 to 11). About 90% of glucose entering the red cell follows this route.<sup>201</sup> The enzymes catalyzing these reactions have all been found in erythrocytes, and normal values have been reported by several groups.<sup>171-217</sup>

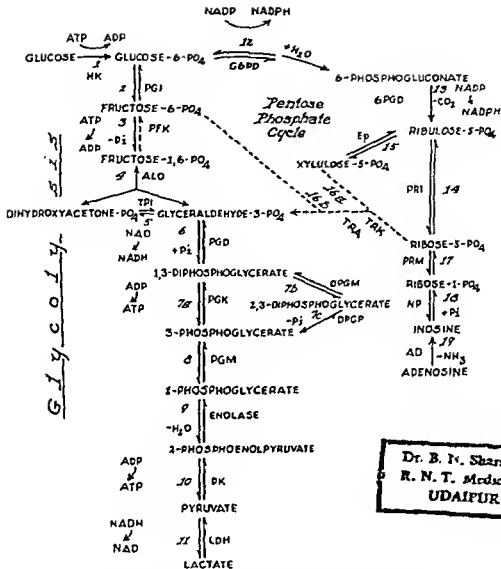

Two important products are formed during anaerobic glycolysis. One of these is reduced nicotinamide-adenine dinucleotide (NADH, DPNH) (Fig. 3-14, reaction 6) a compound essential for the reduction of methemoglobin (page 105). The other is the major high-energy compound in erythrocytes, adenosine triphosphate (ATP). For each mole of glucose catabolized, two moles of ATP are utilized (Fig. 3-14, reactions 1 and 3) and a maximum of four may be produced (two moles in reaction 7a and two in reaction 10). Thus, at maximum efficiency, a net yield of two moles of ATP may be expected for each mole of glucose completing the series of reactions. This net yield may be decreased, however, by a side pathway unique to the red cell, the 2,3 diphosphoglycerate (2,3 DPG) pathway (Fig. 3-14, reactions 7b and 7c), also known

as the Rapoport-Luebering shunt after its discoverers.<sup>209</sup>

The principal phosphorylated intermediate in erythrocytes is 2,3 DPG, accounting for about two thirds of the red cell phosphorus. In contrast, 2,3 DPG is present in only trace amounts in other tissues. The production of 2,3 DPG constitutes a sort of "energy clutch" because it diverts 1,3 DPG from a step in which ATP is synthesized (reaction 7a, Fig. 3-14) to one in which a high-energy phosphate is "wasted" (reaction 7b). The proportion of 1,3 DPG following the ATP pathway as opposed to the 2,3 DPG pathway appears to be related largely to cellular ADP and ATP levels; when ATP falls and ADP rises, a greater proportion of 1,3 DPG is converted through the ATP-producing step. This mechanism serves to assure a supply of ATP to meet cellular needs.

Early theories for the function of 2,3 DPG in the red cell stressed its role as a buffer and as a short-term storage compound that could be utilized during periods of glucose deprivation. It is now apparent that 2,3 DPG has another role unrelated to energy metabolism; it affects tissue oxygen delivery by reversibly combining with deoxygenated hemoglobin and decreasing hemoglobin oxygen affinity (page 107).

The other pathway of erythrocyte glucose metabolism is the aerobic, pentose phosphate pathway (PPP; also known as the hexose monophosphate shunt or the phosphogluconic acid oxidative pathway) (Fig. 3-14, reactions 12 to 15). Under normal circumstances about 10% of red cell glucose is metabolized aerobically.<sup>201</sup> For many years it has been known that the proportion of glucose metabolized in the erythrocyte via the PPP could be greatly increased *in vitro* by adding methylene blue. Methylene blue has no clear physiologic equivalent; however, a number of other substances may have a similar effect, including cysteine, ascorbate, pyruvate, primaquine, and others.<sup>174,226</sup> The relative activity of the PPP appears to be regulated largely by the concentration of oxidized glutathione (GSSG); when GSSG concentration increases, there is a corresponding increase in

(Prepared with the advice of Dr. G. W. E. Plaut.)

the amount of glucose that enters the PPP.<sup>186</sup>

The principal high-energy product of aerobic glucose metabolism via the PPP is reduced nicotinamide-adenine dinucleotide phosphate (NADPH, TPNH) (Fig. 3-14, reactions 12 and 13). The erythrocyte lacks the machinery to utilize NADPH for energy; instead, NADPH serves as a cofactor in the reduction of glutathione.

### Glutathione Metabolism

In order to survive, the red cell must be able to protect hemoglobin, enzymes, and the membrane from oxidative damage. This function is performed by a system in which reduced glutathione is a key component. Other components of the system include NADPH and the enzymes glucose-6-

ted activity.<sup>189</sup> The investigators suggested that the NADH and NADPH methemoglobin reductases represented different sites on single proteins rather than distinct enzymes. This conclusion is difficult to accept, however, since NADH- and NADPH-methemoglobin reductases can be separated electrophoretically.<sup>184</sup> Also, distinct hereditary syndromes affecting one system but not the other would be difficult to explain on this basis.

### Miscellaneous Enzymes in Red Corpuscles

In addition to the enzymes involved in the glycolytic cycle and in the pentose phosphate pathway, listed in Figure 3-14, many others have been identified and quantitated.<sup>154,162,183,178,193,219,224,229,233</sup> These include: (1) Remnants of Krebs cycle enzymes, including fumarase,<sup>215</sup> malic dehydrogenase,<sup>221</sup> aconitase,<sup>161</sup> and isocitric dehydrogenase.<sup>215</sup> (2) Carbonic anhydrase,<sup>155,211,227</sup> a zinc enzyme occurring in two forms (CA I and CA II), each under independent control of distinct autosomal genes.<sup>227</sup> Carbonic anhydrase catalyzes the reversible formation and dissociation of carbonic acid, thereby contributing to CO<sub>2</sub> transport (page 108). (3) "True" cholinesterase, a membrane-associated enzyme that differs from the relatively nonspecific cholinesterase found in plasma. Cholinesterase is found in far higher concentration in reticulocytes and young red corpuscles than in older ones.<sup>216</sup> (4) Proteolytic enzymes<sup>199</sup> and peptidases.<sup>151</sup> (5) Purine nucleoside phosphorylases specific for nucleosides such as inosine and guanosine.<sup>229,232</sup> (6) Nicotinamide ribonucleoside phosphorylase.<sup>180</sup> (7) Arginase,<sup>157,210</sup> glyoxylase,<sup>175</sup> urease and a thiocyanate oxidase.<sup>179</sup> (8) Adenylate kinase.<sup>167</sup>

Since the production of enzymes is a genetically determined phenomenon, it is to be expected that mutations affecting the activity of various enzymes should occur. Some of these, such as acatalasemia<sup>152,157</sup> and 6-phosphogluconate dehydrogenase deficiency,<sup>165</sup> are associated with no demonstrable abnor-

malities of the red corpuscle. Others may be lethal, thus preventing their recognition. One might have postulated that this would be the case with hexokinase, an enzyme that plays a key role in the metabolism of glucose (Fig. 3-14, reaction 1). This, however, does not appear to be true regarding hexokinase deficiency, and a number of other genetically determined enzyme deficiencies associated with hematologic abnormalities but not necessarily lethal have been discovered. The abnormalities include congenital hemolytic anemias (pyruvate kinase, glucose-6-phosphate dehydrogenase, glutathione reductase, diphosphoglycerate mutase, and triosephosphate isomerase) and hemolytic anemias associated with drug ingestion (G6PD, glutathione reductase). These will be discussed in Chapters 22 and 23.

### Function of the Erythrocyte

One of the most striking examples of the importance of the evolutionary process, as well as of the efficiency of the body economy, is found in the mammalian erythrocyte. Essential to mammalian life is a process of combustion for which a constant supply of oxygen and the simultaneous removal of carbon dioxide are required. The function of the red cell is to mediate the exchange of respiratory gases, oxygen and carbon dioxide, between the lungs and the tissues. In man at rest, about 250 ml of oxygen are absorbed and 200 ml of carbon dioxide are produced per minute. During exercise these quantities increase tenfold. If the respiratory gases were carried in physical solution in the plasma, man's activity could only be one-fiftieth of that actually possible. The development of hemoglobin makes possible the transportation of a hundred times as much oxygen as could be carried by the plasma alone.

In the majority of invertebrates, oxygen-carrying pigment is transported freely in the plasma rather than within cells.<sup>196</sup> This is a relatively inefficient method. Hemoglobin, as a protein free in the plasma, exerts an osmotic pressure about five times greater than that produced by the plasma proteins. By

the inclusion of this pigment in corpuscles the viscosity of the blood is maintained at a low level, water is not drawn from the tissues by it, and the flow of blood containing such a large amount of protein is made possible.

When fully saturated, each gram of hemoglobin binds 1.34 ml of oxygen. The degree of saturation is related to the oxygen tension of the blood, which normally ranges from 100 mm Hg in arterial blood to about 35 mm Hg in veins. The relation between oxygen tension and hemoglobin oxygen saturation is described by the oxygen-dissociation curve of hemoglobin (Fig. 3-16). The characteristics of this curve are related in part to properties of hemoglobin itself and in part to the environment within the erythrocyte, including pH, temperature, ionic strength, and concentration of phosphorylated compounds, especially 2,3 diphosphoglycerate (2,3 DPG).

Oxygen affinity of hemoglobin is generally expressed in terms of the oxygen tension at which 50% saturation occurs, the so-called  $P_{50}$ . When measured in whole erythrocytes, this value averages 27.1 mm Hg in normal, non-smoking males and 27.5 mm Hg in normal, non-smoking females.<sup>228</sup> When oxygen affinity is increased, the dissociation curve is shifted leftward, and the value for  $P_{50}$  is

reduced. Conversely, with decreased oxygen affinity, the curve is shifted to the right and  $P_{50}$  is increased.

With heme polypeptides consisting of a single subunit (eg, myoglobin) the oxygen-dissociation curve is hyperbolic, and oxygen affinity is considerably greater than that of hemoglobin (Fig. 3-16). Such a compound would function poorly in oxygen transport because little oxygen would be released until the tissue oxygen tension became very low. In contrast, the oxygen-dissociation curve of hemoglobin is distinctly sigmoidal, and the steepest part of its slope occurs at levels of oxygen tension corresponding to those found in tissues. This difference between the hemoglobin and myoglobin curves is the result of interaction between the four heme-polypeptide units of hemoglobin (page 176). This phenomenon commonly is referred to as "heme-heme interaction"; however, since no fundamental chemical change occurs in the heme group itself, perhaps the term "subunit interaction" is to be preferred.<sup>229</sup> In essence, subunit interaction leads to a change in affinity for oxygen as each of the four  $O_2$ -binding sites becomes occupied. Affinity for the first  $O_2$  molecule is relatively low, and affinity increases with each molecule bound.

The change in oxygen affinity with pH is known as the Bohr effect.<sup>212</sup> Hemoglobin oxygen affinity is reduced as the acidity increases (Fig. 3-16). Since the tissues are relatively rich in carbon dioxide, the pH is lower than in arterial blood; therefore, the Bohr effect facilitates transfer of oxygen. The Bohr effect is a manifestation of the acid-base equilibria of hemoglobin. The dissociation constant ( $pK$ ) of the reaction  $HHb \rightleftharpoons H^+ + Hb$  is 7.9, whereas after oxygenation, the  $pK$  decreases to 6.7. These changes are important not only for oxygen delivery, but also in carbon dioxide transport (see below).

Another important factor affecting the oxygen affinity of hemoglobin is the concentration of phosphorylated compounds, especially 2,3 DPG.<sup>158,166,168,170</sup> (see page 102). In the deoxygenated state, hemoglobin can bind 2,3 DPG in a molar ratio of 1:1, a reaction leading to reduced oxygen affinity.

Fig. 3-16. Oxygen-dissociation curve of hemoglobin, at three values for pH, compared with that of myoglobin.  $pO_2$ , Partial pressure of oxygen,  $pCO_2$ , partial pressure of carbon dioxide

The increased oxygen affinity of fetal hemoglobin appears to be related to its lessened ability to bind 2,3 DPG.<sup>231</sup>

The increased oxygen affinity of stored blood is accounted for by reduced levels of 2,3 DPG.<sup>169</sup> Transfusion of such blood results in an in vivo increase in oxygen affinity that returns toward normal in several hours as the function of the glycolytic pathway is restored. The reduction in 2,3 DPG levels in stored blood can be mitigated by adding inosine or phosphate to the storage solutions.<sup>206</sup>

Changes in 2,3 DPG levels play an important role in adaptation to hypoxia. In a number of situations characterized by hypoxemia, red cell 2,3 DPG levels increase, oxygen affinity is reduced, and delivery of oxygen to tissues is facilitated. These include abrupt exposure to high altitude,<sup>195</sup> anoxia due to pulmonary or cardiac disease,<sup>203,235</sup> blood loss,<sup>176</sup> and anemia.<sup>225</sup> Increased 2,3 DPG also plays a role in adaptation to exercise.<sup>205</sup>

The factors controlling erythrocyte 2,3 DPG levels have not been defined completely. However, probably the most important one is the overall rate of glycolysis.<sup>213,228</sup> Glycolysis is stimulated by alkalosis and depressed by acidosis,<sup>158,171</sup> probably because of an effect of pH on phosphofructokinase (Fig. 3-14, reaction 3).<sup>207</sup> Thus, the respiratory alkalosis that occurs with ascent to high altitude could lead to increased rates of glycolysis and increased 2,3 DPG levels. Also, intracellular alkalosis might occur with excessive hemoglobin deoxygenation because of the Bohr effect. Another possible mechanism is diversion of 1,3 DPG to the 2,3 DPG pathway (Fig. 3-14, reaction 7b). Such a diversion might be accomplished by an increase in deoxygenated hemoglobin, which in turn binds 2,3 DPG and relieves end product inhibition of 2,3 DPG mutase.<sup>204</sup>

Molecular mechanisms for explaining subunit interaction, the Bohr effect, and the 2,3 DPG effect are discussed in Chapter 4 (page 176).

Transport of carbon dioxide by red cells, unlike that of oxygen, does not occur by direct binding to heme.<sup>225</sup> In aqueous solutions, carbon dioxide undergoes a pair of

reactions:

Carbon dioxide diffuses freely into the red cell where the presence of the enzyme *carbonic anhydrase* facilitates reaction 1. The  $\text{H}^+$  liberated in reaction 2 is accepted by deoxygenated hemoglobin, a process facilitated by the Bohr effect. The bicarbonate formed in this sequence of reactions diffuses freely across the red cell membrane and a portion is exchanged with plasma  $\text{Cl}^-$ , a phenomenon called the "chloride shift." About 70% of tissue carbon dioxide is processed in this way. Of the remaining 30%, 5% is carried in simple solution and 25% is bound to deoxygenated hemoglobin amino acid groups, forming carbamino-hemoglobin.

Alterations in the oxygen dissociation curve occurring in various hemoglobinopathies will be discussed in Chapter 30 (page 982).

### Erythrocytes of Various Mammals and Lower Vertebrates

Differences in number, size, and morphologic characteristics of the red blood corpuscles of the lower vertebrates and those of the mammalia furnish further evidence of the efficiency attained through the evolutionary process. With the exception of the antarctic ice fish and the larvae of certain eels, all vertebrate species possess erythrocytes.<sup>197</sup> Most vertebrate red cells are nucleated and have a capacity for aerobic, oxidative metabolism. The occurrence of a denucleated cell that is dependent on anaerobic glycolysis for energy and is rich in 2,3 DPG is a late evolutionary development, characteristic of mammals.

Differences in the mass of red corpuscles, as represented by the volume of packed red cells, are relatively small throughout the vertebrate phylum<sup>234</sup> (Fig. 3-17). Correspondingly, the range in amount of hemoglobin per unit volume of blood is small, being actually no greater than that found in anemia. There is, in other words, a relatively constant

Mean Corpuscular Hemoglobin Concentration

Number of Red Corpuscles

Fig. 3-17. The red corpuscles of various vertebrates vary greatly in number per liter as well as in mean corpuscular volume and mean corpuscular hemoglobin. However, there is comparatively little variation in volume of packed red cells or in blood hemoglobin concentration and almost none in the mean corpuscular hemoglobin concentration.

amount of hemoglobin available for the transportation of oxygen in most vertebrates. However, the differences in the number and kind of vehicles that transport this hemoglobin are extraordinarily great. In the vertebrate phylum, erythrocyte counts as low as  $0.021 \times 10^{12}/l$  (in a tailed amphibian, *Amphiuma*) and as high as  $17.9 \times 10^{12}$  (in the goat) have been found.<sup>234</sup> The size of the red corpuscles is inversely proportional to the red cell count, the corpuscles of one of the tailed amphibia measuring almost 15,000 fl, while those of the goat measure 19 fl. In Figure 3-18, the red corpuscles of human blood and those of the "Congo Snake," a tailed amphibian, are compared. (See also Table B-2, Appendix B.)

The excessively large corpuscles of the lower vertebrates probably are transported less readily through the blood vessels than are the smaller corpuscles of mammalia. What is still more important, the small size of the corpuscles of mammals is adapted for the maximal development of surface. For the gaseous exchanges that occur through the

mediation of the erythrocyte, this is extremely important.<sup>183</sup>

The biconcave shape of the erythrocyte has been shown to be the best shape whereby in- and out-going gases may reach and leave all parts of the corpuscle with the least variation in time.<sup>181</sup> The efficiency of the mammalian red cell is favored by its plasticity<sup>101</sup> and the absence of a nucleus. Although the red cell is by no means metabolically inert, as was once assumed (see page 102) its oxygen consumption is only 0.5% of that of nucleated red cells<sup>190</sup> and less even than that of reticulocytes.<sup>208</sup> Thus it consumes but little of the gas it transports.

## Laboratory Evaluation of Erythrocytes

### Measures of Concentration

Determination of the concentration of red cell elements in the blood is required for the purpose of detecting anemia or polycythemia

Fig 3-18 The giant nucleated erythrocytes of a tailed amphibian (*Amphiuma means*) compared with human red corpuscles. A polymorphonuclear leukocyte is also shown (Drawing of a slide stained with Wright's and magnified  $\times 960$ )

or in order to calculate erythrocyte indices (page 115). The measures of concentration fall into three groups: those for determining the volume of packed red cells (VPRC), the blood hemoglobin concentration (Hb), and the red cell count (RBC). Red cell counting methods are discussed in Chapter 1 (page 9).

### Volume of Packed Red Cells

The VPRC is determined by centrifugation of blood in a container known as a hematocrit. Various early types of hematocrits were introduced in the latter part of the 19th century by Hedin,<sup>329</sup> Blik, and Daland.<sup>316</sup> These instruments, as well as that designed by Van Allen,<sup>326</sup> were inaccurate, partly because leakage often occurred at the distal ends during centrifugation and also because optimal conditions for time and force of centrifugation were not established. These sources of error were eliminated in 1929 by Wintrobe hematocrit (Fig. 3-19) and the specifications established for its use. Methods

currently in use for determining the VPRC include the original Wintrobe or macro method and more recently described micro methods. In addition, approximations of the "hematocrit" can be made by determining the conductivity of blood or by calculations based on the number and size of red cells as determined with an electronic particle counter. The last two methods are described in Chapter 1 (pages 14 and 20).

In the Wintrobe (macro) method the hematocrit is filled with anticoagulated blood by means of a capillary pipet and centrifuged for 30 minutes. The object of centrifugation is to secure optimal packing of the erythrocytes so that a minimal and reproducible amount of plasma remains between them, and yet distortion or expulsion of some of their contents does not occur. For this purpose, a relative centrifugal force (RCF) of  $2260 \times$  gravity (G) is employed. RCF depends upon the distance of the particle from the center of revolution (radius,  $r$ ) as well as upon the speed of centrifugation in revolutions per minute (RPM). This relationship is

indicated by the formula:

$$RCF = 0.000,011,18 \times r \times (RPM)^2$$

The radius ( $r$ ) is defined as the distance (in cm) from the center of the drive shaft of the centrifuge to the bottom of the hematocrit tube as it is held horizontally in the centrifuge cup. The method was standardized with a No. 2 International Centrifuge and a centrifuge head with a radius of 22.5 cm, which, at 3000 RPM will produce an RCF of  $2264 \times G$ . Since centrifuge heads with quite different radial distances may be used, it is necessary to determine, for each, the speed that must be attained to produce the desired RCF. Substituting in the formula given above an RCF of  $2260 \times G$ , the equation may be

written:

$$RPM = \sqrt{\frac{202,146,700}{r \text{ (cm)}}}$$

Thus, by measuring the radius of a particular centrifuge head, one may calculate the speed of centrifugation required to achieve the necessary RCF. The RPM should be determined by means of a tachometer since the attainable speed indicated on the face of the centrifuge is not necessarily correct.

Maximal packing of the erythrocytes is achieved after 30 minutes of centrifugation. Prolongation of the time of centrifugation does not compensate for an inadequate RCF. Unless the centrifuge is capable of producing the number of revolutions per minute required by its radius to attain the necessary RCF, centrifugation even for several hours will not produce optimal packing.

The VPRC may be read directly from the scale embossed on the Wintrobe tube, which is divided into centimeters and millimeters. If the hematocrit has been filled to "10" (Fig. 3-20), the level at which the packed red corpuscles are found, if multiplied by 0.1, will give the volume in liters per liter (l/l) of blood.

At the uppermost level of the packed red cells, immediately adjacent to the reddish-gray layer of packed white corpuscles, a narrow black band will be seen. This represents a layer of erythrocytes in which the oxyhemoglobin has been reduced by the metabolic activity of the leukocytes.<sup>301</sup> The reading of "volume of packed red cells" is made at the uppermost level of the black line.

Determination of the VPRC in the Wintrobe tube has the advantage of yielding useful additional information with little extra effort. This includes the sedimentation rate (ESR, page 125), the icterus index (Chapter 5, page 214), and the volume of packed white cells and platelets. Above the deep red layer of packed red corpuscles, a reddish-gray layer of packed leukocytes and platelets is found (Fig. 3-20). In normal blood this ranges from 0.5 to 1 mm in thickness, each 0.1 mm corresponding approximately to  $1.0 \times 10^9$ /leuko-

Fig. 3-19. Wintrobe's hematocrit, pipet and bulb used for filling it, and cap for hematocrit. Two thirds actual size

**Fig 3-20** Photographs of hematocrits containing blood from patients with leukemia and polycythemia. **A**, Chronic lymphocytic leukemia: volume of packed WBC and platelets 0.265 l per liter of blood. VPRC, 0.205 l. The leukocyte count was  $900 \times 10^9/l$ , platelets numbered  $180 \times 10^9/l$  erythrocytes  $2.33 \times 10^{12}/l$ . **B, C**, Chronic myelocytic leukemia. The respective erythrocyte counts were 4 and  $2.3 \times 10^{12}/l$  but the leukocyte and platelet counts were approximately the same (WBC  $42 \times 10^9/l$  and  $35 \times 10^9/l$  respectively, platelets  $360 \times 10^9/l$  and  $325 \times 10^9/l$ ). **D**, Erythremia showing an increase in all the corpuscles of the blood. RBC  $5.7 \times 10^{12}/l$ , WBC  $24.4 \times 10^9/l$ , platelets  $430 \times 10^9/l$ . The successive layers of packed platelets, leukocytes, and red corpuscles are particularly clear in **B, C**, and **D**.

cytes. Thus, when the platelet count is approximately normal, the thickness of this reddish-gray layer may be used as a rough index of the leukocyte count. When the leu-

kocyte count is greater than  $12.0 \times 10^9/l$  the correlation between the thickness of the leukocyte layer and the white cell count is less accurate than when the count is below this value; but even for counts as high as  $30.0 \times 10^9/l$  the thickness of the reddish-gray layer is a remarkably useful guide. When leukocytosis is marked, relatively more packing of leukocytes tends to occur than in normal blood and 0.1 mm corresponds more nearly to  $2.0 \times 10^9/l$  than to  $1.0 \times 10^9/l$ .

The thickness of the layer above the packed red corpuscles depends on the number of leukocytes, the kind of leukocytes, and the quantity of platelets. Since lymphocytes are smaller than the cells of the myeloid series, when there is relative lymphocytosis the layer will be narrower for a given quantity of corpuscles than when myeloid leukocytes predominate. Again, if the platelets are reduced in number the layer is correspondingly narrower. In leukopenia, and particularly when this is accompanied by thrombocytopenia, the layer of corpuscles above the red cells is barely perceptible. On the other hand, when the platelets are more numerous than usual, and sometimes even when they are present in normal numbers, it is possible to distinguish two portions in the layer above the red corpuscles (Fig. 3-20, B, C, D). Uppermost will be found a cream-colored layer which, on aspiration smear and microscopic examination (Fig. 3-21), is found to consist practically entirely of platelets. The reddish-gray layer below this consists almost exclusively of leukocytes (Fig. 3-22). In chronic myelocytic leukemia and in erythremia, in which both the number of leukocytes and the quantity of platelets are increased, the three well-defined layers of corpuscles present a striking picture (Frontispiece, Plate I). Separation of the corpuscles into layers is aided by a period of sedimentation preceding centrifugation.

Observation of the color and opacity of the blood plasma will reveal degrees of jaundice that are not sufficiently marked to be perceived by physical examination. The *icterus index* of the plasma is easily measured in the hematocrit tube by comparison with stand-

Fig. 3-21. Microscopic view of the topmost cream-colored layer in the hematocrit shown in Figure 3-20. C It is composed almost entirely of platelets ( $\times 700$ )

ards in tubes of the same size (Chapter 5, page 215). Lipemia also is easily detected, the plasma appearing quite opaque in this condition. Other plasma abnormalities may be discovered occasionally, such as cryoglobulins in multiple myeloma.<sup>352</sup>

The micro method for determining

Fig. 3-22. The reddish-gray layer below the cream-colored layer in the hematocrit shown in Figure 3-20. B and D. It is composed almost entirely of leukocytes ( $\times 700$ )

VPRC<sup>310</sup> has the advantage of requiring smaller amounts of blood, shorter centrifugation times, and smaller, less expensive centrifuges than the macro method. The determination is performed in capillary tubes that are of uniform bore and usually open at both ends.<sup>337,339</sup> The tubes usually are sealed with clay (less often, with heat) prior to centrifugation. Tubes containing dried heparin are available so that capillary blood may be used without prior anticoagulation. A variety of microhematocrit centrifuges can be obtained from commercial sources; most of them are small, portable, and inexpensive. These instruments exert a RCF of 11,000 to 15,000  $\times G$ , but speed is not controllable and no tachometer is provided. The only control is a time switch. Maximal packing usually is achieved after five minutes of centrifugation. The microhematocrit tubes have no scale of their own and must be inspected with any of several calibrated devices in order to read the VPRC. Because of the high RCF, the value usually is slightly lower (0.01 to 0.03 l/l) than that obtained with the macro method.

The micro methods have certain disadvantages as compared with the standard Wintrobe method. Most important of these is the reading error which, although negligible at normal levels for the VPRC, approaches 5% ( $\pm 2$  CV) at low levels.<sup>310</sup> Additional variability may be introduced by the use of capillary blood samples. Furthermore, the separation of leukocytes from the packed red cell column is less complete, especially when there is marked leukocytosis. The microhematocrit is therefore less reliable than the macro method for calculation of the erythrocyte indices.<sup>310</sup> Finally, sedimentation rate, icterus index, and the volume of packed white cells and platelets cannot be determined in the capillary tubes. These disadvantages tend to be minor ones, however, and for the routine detection of anemia and polycythemia as well as for the serial observation of fluctuations in these findings, the method is satisfactory<sup>224</sup> and is particularly well suited to the small laboratory, such as that in many doctor's offices.

### Accuracy of Hematocrit Methods

For the VPRC to be a perfectly accurate indication of the proportional volume of blood occupied by erythrocytes, the conditions of centrifugation would have to be such that no plasma remains in the red cell column, and yet none of the cellular contents is expressed.

Plasma trapping has been measured by dilution of a plasma label, such as  $^{131}\text{I}$ -albumin. These studies have demonstrated that when centrifugation is carried out as specified for the Wintrobe (macro) method, an average of 2.13% of the red cell column represents trapped plasma.<sup>319</sup> This amount may vary somewhat at different VPRC values; thus, no plasma trapping could be demonstrated at values less than 0.33 l/l, but there was 2% trapping at 0.50 l/l and 4% at 0.68 l/l.<sup>319</sup> These differences presumably reflect the fact that the effective radius, and therefore the RCF, vary somewhat with the height of the red cell column. Somewhat more plasma is trapped if the red cells are spherocytes.<sup>323</sup>

For the purposes of detecting anemia or calculating erythrocyte indices a correction for trapped plasma usually is not made. For these purposes the important considerations are that the precision of the method is high and that the normal values in use today were established without such corrections. How-

ever, allowances for trapped plasma often are made when the VPRC is used in calculating total blood volume (page 122).

As previously noted, the values for VPRC obtained with the micro method are slightly lower than with the macro method because of the greater centrifugal forces applied in the micro method. Surprisingly, however, the amount of plasma trapping in microhematocrits was found to be of the same order of magnitude as that found with the Wintrobe method.<sup>321</sup> An increased amount of plasma trapping was found in some anemias, especially hypochromic anemias and sickle-cell anemia.

### Hemoglobin Concentration

Prior to 1959, blood hemoglobin concentration was measured by a variety of methods.<sup>310,320,331,332,333,339,344,348,353</sup> These have been superseded in almost all laboratories by spectrophotometric or colorimetric assays based on the conversion of hemoglobin to cyanmethemoglobin.<sup>306,310,315</sup> The major reason for the nearly universal acceptance of the cyanmethemoglobin method is the availability of stable, accurate standards.<sup>309</sup> Standards that carry the certification of the College of American Pathologists are available from several commercial sources. These have an approximate content of 60 mg cyanmethemoglobin per deciliter (dl) of solution,

Table 3-5. Comparison of Methods for Measuring Concentration of Red Cell Elements in Blood<sup>310</sup>

Method	Error <sup>1</sup>	Blood Required	Time Required (Min)	Equipment Cost	Additional Data Available
VPRC (macro)	1.9%	1.0 ml	35	High	Yes <sup>3</sup>
VPRC (micro)	2% <sup>2</sup>	Drop	10	Moderate	No
Hb (cyanmethemoglobin)	1.2%	Drop	20	High	No
Hb (Sahl's or Spencer)	10%	Drop	10-30	Low	No
RBC (hemocytometer)	9%	Drop	30	Low	No
RBC (electronic method)	3.6%	Drop	15	Highest	Yes <sup>4</sup>

2 At normal levels—increases to about 5% at low values

3 Sedimentation rate, icterus index, volume of packed leukocytes and platelets

4 Depending on the instrument size, distribution curves, automatic MCV calculation, and VPRC calculation from Cartwright<sup>310</sup> courtesy of the author and Grune & Stratton

corresponding to the dilution used in most clinical laboratories (1:251 of blood with a hemoglobin content of 15.0 g/dl). The standards can be used for at least a year from the date of production. Another advantage of cyanmethemoglobin is its broad absorption band in the region of 540 nm. The millimolar extinction coefficient of cyanmethemoglobin at this wavelength is taken to be 44.0.<sup>343</sup> A wide variety of satisfactory spectrophotometers and filter photometers are available.

To prepare cyanmethemoglobin, hemoglobin is reacted with ferricyanide and cyanide. Ferricyanide converts hemoglobin to methemoglobin, which then combines with cyanide to form cyanmethemoglobin. These two reactions are rapid and stoichiometric. The usual diluent in routine laboratories is Drabkin's solution, which consists of 1.0 g  $\text{NaHCO}_3$ , 50 mg potassium cyanide, and 200 mg potassium ferricyanide in 1.0 l distilled water. This is a clear solution, pale yellow in color. It should be kept in a brown bottle and a fresh solution should be made up once a month. The concentration of cyanide in the reagent is so low that as much as 4 l would be required to produce a lethal effect in man.

An accurately measured volume of blood is diluted in an accurately measured volume of the diluent. For most photometers 20  $\mu\text{l}$  blood is added to 5 ml of diluent, a 251-fold dilution. The optical density at 540 nm of this solution is directly proportional to the concentration of the pigment. The result should be expressed in terms of grams of hemoglobin per deciliter of blood (g/dl). The use of a scale based on "percent of normal" is discouraged.

Two other methods currently in use depend on visual colorimetry. They are considerably less accurate than the spectrophotometric assay and are used only because of their low cost and the portability of the apparatus. Oxyhemoglobin is the pigment measured in the *Spencer hemoglobinometer*. A hemolysed sample of blood, placed in one half of a glass chamber, is compared by transmitted green light from a battery-lit bulb with a variable standard on a split screen.<sup>310</sup> This permits matching in a color

range to which the human eye is more sensitive, as compared with red. ~

In the *Sahli hemoglobinometer*<sup>310,339</sup> blood is diluted with 0.1 N hydrochloric acid, the hemoglobin of the blood being thus converted to acid hematin which is brown in color. The resulting mixture is then diluted with water until a match with the brown glass standard is attained, and the hemoglobin value is read from the scale by noting the height of the column of the diluted acid hematin.

### Comparison of Methods

The most important characteristics of the various measures of red cell concentration are tabulated in Table 3-5. It is apparent that the error of the red cell count by the hemocytometer method and that of hemoglobin by the Sahli or Spencer methods are great enough to make them unsatisfactory except where cost and portability of equipment are overriding factors.

If a satisfactory specimen of anticoagulated blood can be obtained, the VPRC by the macro method is the most useful, single determination. Not only is it simple and accurate, but with little extra effort additional useful data are available. The microhematocrit is a satisfactory, alternative screening procedure if only limited amounts of blood are available. Its principal disadvantage is that its error increases at low values. Measurement of hemoglobin by the cyanmethemoglobin method is also an excellent screening method. Although the red cell count by electronic methods can be used to detect anemia, its chief application is in the calculation of red cell indices, as described below.

### Indices of Red Cell Size and Hemoglobin Concentration

It was not until more than two centuries after Leeuwenhoek compared the diameter of red corpuscles with that of a grain of sand that further attempts were made to study the size of these cells. Thomas Young, in 1813, and Piiper, more than a century later (1919), showed the value of the principle of diffrac-

tion for the measurement of small objects, including red cells. It was not until the latter half of the 19th century that the diameter of red corpuscles in various diseases was measured and the significance of variations in the size and hemoglobin content of these cells began to be appreciated. In 1864, Welcker demonstrated that the diameter of the red cells in chlorosis is less than normal, and, in 1876, Sorensen pointed out that an increase in the size of the cells is one of the most characteristic features of the blood in pernicious anemia. Hayem introduced the color index in 1878. Malassez described the normal variation in the diameters of red corpuscles, and also calculated the "titre hémoglobique" to micromicrograms. Following the introduction of the hematocrit, Capps introduced the volume index (1903) and made important observations concerning the anemias. Price-Jones' pautostaking measurements of the diameters of red cells, which are responsible for the attention that ultimately came to be paid to cell size, were commenced in 1910. The relationship of hemoglobin to volume of cells attracted Malassez' interest and similar studies were made by Hart (1881) and by Herz and Bonninger (1919). Haden introduced the term "saturation index" (1923). The terms "mean corpuscular volume," "mean corpuscular hemoglobin," and "mean corpuscular hemoglobin concentration" and methods for their calculation were introduced in 1929 by Wintrobe.<sup>351</sup>

#### Determination of Erythrocyte Size

**DIAMETER.** The measurement of cell diameter can be accomplished by measuring the individual cells, by measuring their diffraction patterns, or by the use of an image-splitting microscope eyepiece.

The method used by Price-Jones<sup>342</sup> in his pioneer studies is relatively accurate but laborious. It consisted of the projection of a stained blood film on paper, outlining the cells in pencil, and measurement of the maximum and minimum diameters of each of 500 or 1000 cells. Less time-consuming modifications have been devised.<sup>340,349</sup> A simpler

Fig 3 23. Micrometer disk (Courtesy of Carl Zeiss, Inc)

but less accurate method consists in the direct measurement of the cells as seen in the microscope by means of a disk on which a scale has been etched (micrometer disk, Fig. 3-23). The disk is inserted into the eyepiece of the microscope, and the scale must be calibrated in relation to the magnification of the microscope being used. The diameters of the erythrocytes may be recorded graphically to show the number of cells of various sizes. This has come to be known as the "Price-Jones curve" (Fig. 14-4, page 570).

The English workers found that mean cell diameter, as measured by a modification of the Price-Jones method,<sup>350</sup> can be carried out with considerable precision.<sup>304</sup> However, the time required to perform the measurements seriously limits the utility of the procedure.

The *diffraction method* for measuring mean corpuscular diameter depends on the fact that a beam of white light passing through a film containing numerous small particles is diffracted by the edges of these particles to produce a set of colored, concentric circles. With an appropriate optical system the individual spectra can be made to coincide, and from the radius of the yellow circle the mean cell diameter can be calculated. This method was introduced by Pijper in 1919.<sup>341</sup> Since that time, numerous instruments, all based on the same principle, have been described.<sup>302,311,327,328</sup>

Still another way to obtain a size distribution of erythrocyte diameters involves the use of the *Watson image-splitting eyepiece*.<sup>312</sup> With this instrument, manipulation of the control knob separates the cell image into two overlapping images. Rotation of the knob can be continued until the split images separate

far enough to just touch. The degree of movement is recorded and converted to vertical diameter by means of a calibration factor. This technique can be used for rapid screening for cell size or for the construction of a Price-Jones curve.

**VOLUME.** The mean volume of the red corpuscles may be calculated from the erythrocyte count and the VPRC by means of the formula,

Mean corpuscular volume (MCV) =

$$\frac{\text{vol. packed red cells (l/l)} \times 1000}{\text{red cell count} (\times 10^{12}/\text{l})}$$

This formula was designed in order that the result may be expressed in femtoliters (fl;  $10^{-15}$  l).

Example: RBC,  $3.58 \times 10^{12}/\text{l}$ , VPRC, 0.39 l/l

Then,  $\text{MCV} = \frac{390}{3.58} = 109 \text{ fl}$

The electronic cell counter (Chapter 1, page 13) can be employed to record cell volume distribution curves.<sup>308,313 314,324 336,345</sup>

This is done by varying the upper and lower thresholds systematically and recording the differences in counts in these various electronic "windows." To obtain absolute values, the relation of the window number to cell volume must be known. A method also has been described for the determination of frequency distribution curves of red cell volumes by the use of a 100-channel pulse height analyzer.<sup>334</sup> Cell volume distribution curves have also been constructed with photoelectric measurements of the sedimentation of erythrocytes in a dilute suspension of Ringer's solution.<sup>325</sup>

**THICKNESS.** The thickness of red corpuscles, like their diameter, can be measured microscopically as they lie on edge in wet films, as well as by a cellophane section method.<sup>346</sup> The mean thickness may also be estimated from the mean corpuscular volume and the mean diameter, by regarding the cells as short cylinders. Thus,

Mean corpuscular thickness (MCT) =

$$\frac{\text{mean corpuscular volume}}{\pi \left( \frac{\text{mean diameter}}{2} \right)^2}$$

### *The Estimation of the Hemoglobin Content of the Red Cells*

Measurements of the hemoglobin content of the red cells are necessarily indirect and are derived from the blood hemoglobin concentration, the red cell count, and the volume of packed red cells.

The ratio of hemoglobin to red cell count, which indicates the amount of hemoglobin in the average corpuscle, may be expressed in absolute terms.

Mean corpuscular hemoglobin (MCH) =

$$\frac{\text{hemoglobin (g/l)}}{\text{red cell count} (\times 10^{12}/\text{l})}$$

The formula has been calculated so that the result is expressed in picograms (pg; equivalent to  $\mu\text{g}$  or  $10^{-12}$  g).

Example. RBC,  $3.6 \times 10^{12}/\text{l}$ , hemoglobin, 13.6 g/dl

Then, mean corpuscular hemoglobin is  $\frac{136}{3.6} = 38 \text{ pg}$

Another important ratio, as will be shown in the chapters on the anemias, is that of hemoglobin to volume of packed red cells. This measures the concentration of hemoglobin in the average red corpuscle.

Mean corpuscular hemoglobin concentration (MCHC) =

$$\frac{\text{hemoglobin (g/dl)}}{\text{vol packed red cells (l/l)}}$$

The result is expressed in grams of hemoglobin per decaliter of packed red cells (g/dl).

Example: Hemoglobin, 13.6 g/dl, vol packed red cells, 0.39 l/l of blood

Then, mean corpuscular hemoglobin concentration

$$= \frac{13.6}{0.39} = 35 \text{ g/dl}$$

With the aid of the nomogram shown in Figure 3-24 or by the use of a slide rule<sup>203,310</sup> the erythrocyte indices can be calculated easily.

The difference between mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) should be clearly understood. The former measures the weight of hemoglobin in the average red

Fig 3-24 Nomographic alignment chart for reading of red cell indices. For mean corpuscular volume (MCV) join the value for red cell count and volume of packed cells (VPRC) by means of a ruler, preferably a transparent one (A very satisfactory one is prepared by scratching a straight line on a strip of clear x-ray film and filling it in with ink). The reading is made where the line intersects MCV. Similarly, where a line joining RBC and hemoglobin intersects MCH the reading for mean corpuscular hemoglobin is made, where a line joining hemoglobin and VPRC intersects MCC the reading for mean corpuscular hemoglobin concentration is made. Note that the left side of the hemoglobin scale is used for MCH, the right side for MCC (Prepared by Dr Robert E. Mason.)

corpuscle and expresses the results in parts of a gram (picograms). The latter (MCHC) indicates the *concentration* of hemoglobin in the average red corpuscle, ie, the ratio of weight of hemoglobin to the volume in which it is contained, and the result is expressed in

g/dl. The distinction is an important one. In the *normochromic* anemias, increases or decreases in the average size of the red corpuscles (MCV) are associated with corresponding increases or decreases in the weight of hemoglobin (MCH) carried in the corpus-

cles, but the concentration of hemoglobin (MCHC) remains normal. In the *hypochromic* anemias (Chapter 16), however, the reduction in the weight of hemoglobin in the average corpuscle is even greater than the decrease in the average cell size; thus, the MCHC is subnormal.

Except in hereditary spherocytosis (page 753), and sometimes in homozygous sickle-cell and Hgb C diseases, the MCHC does not exceed 37 g/dl. Thus, the term *hyperchromic* is rarely appropriate. The value of 37 g/dl is near the upper limits of solubility of hemoglobin and further concentration might be expected to result in crystallization.

Now outmoded is the *color index*, which expresses the average amount of hemoglobin in the red cell in relation to arbitrarily chosen normal values for hemoglobin and red cell count. It was a misunderstanding as to the meaning of this index that led to a mistaken impression regarding the hemoglobin concentration in the red cells in pernicious anemia. Because the color index is increased in this disease it was incorrectly assumed that the red corpuscles in this condition were "hyperchromic" or supersaturated with hemoglobin. It is true that the amount of hemoglobin in the average cell, as measured by MCH or by color index, is increased, but only in proportion to the increase in the average size of the cells. The MCHC is not increased. The darker than normal appearance of these corpuscles when examined under the microscope, and the lack of the normal central pallor, are due to their increased thickness.

### Reproducibility of the Red Cell Indices

The MCV, MCH, and MCHC are sometimes referred to collectively as the red cell indices or the corpuscular constants. The former term is to be preferred since these measures are not "constants" in the usual sense of the word. With skilled technicians using the preferred methods, the red cell indices can be determined with a high degree of precision (Table 3-6). Obviously, the use of less precise or less accurate methods increases the error of these indices.

It must be emphasized that the degree to which the values are to be relied upon relates not only to the methods employed, but also to the skill and care with which they are performed. Undoubtedly, in all instances, whether the technique is beyond criticism or where it is only mediocre, the examination of the blood smear by the physician himself is extremely important. In this way, gross errors are not likely to pass unnoticed and a visual picture of the morphologic appearance of the blood can be obtained; in addition, sometimes important information may have been overlooked by persons less directly interested in the patient.

### Staining and Enumeration of Reticulocytes

New Methylene Blue N (Color Index 52030) is superior to the classic brilliant cresyl blue because of its uniform performance and the sharp, blue staining of the reticulum.<sup>307,317</sup> In making the reticulocyte count, all red corpuscles that contain blue staining threads or granules are counted. In relatively mature reticulocytes, only a few blue granules or scattered threads will be found, but these should still be classed as reticulocytes. The percentage among 500 or, better still, 1000 red corpuscles is counted. An accurate estimate can be made only if the red corpuscles are distributed evenly, without overlapping

Table 3-6. Reproducibility of the Red Cell Indices\*

Index	Method Used for RBC	Error (%) ( $\pm 2$ CV)

clumps or rouleaux. There should be no visible conglomeration at the free edges.<sup>375</sup>

The margin of error in reticulocyte counting is great. It is greatest when counts are made on different preparations by different observers and is large even when they are done on the same preparation by different observers. The range of values may be as great as 100% above or below the mean value. Repeated reticulocyte counts by the same observer on the same specimen of blood vary less. It is desirable, therefore, that the same observer make all the counts on any one patient. Reticulocytes may be expressed as percent of red cells, or this figure may be multiplied by the red cell count to yield an "absolute number" (reticulocytes  $\times 10^9/l$ ). Methods for "correcting" the reticulocyte count for anemia and for premature release ("shift") are discussed in Chapter 20 (page 731).

Techniques for determining the "absolute number" of reticulocytes with the hemocytometer<sup>122</sup> have not been very satisfactory because, at the magnification that can be used with the ordinary objective, reticulocytes cannot be made out readily. Björkman,<sup>305</sup> however, introduced a method whereby reticulocytes are first stained in a capillary pipet, and afterwards are fixed in a diluent consisting of 0.30% potassium thiocyanate (KSCN) in 0.05 normal sulfuric acid. The fixation process is attended by an escape of hemoglobin from the red cells which allows them to show up more clearly than otherwise.

The speed and accuracy of reticulocyte counts are increased in a method that takes advantage of the fact that the reticulum is composed largely of RNA. Acridine orange combines with RNA and the resulting complex is seen as an orange-red fluorescence when exposed to ultraviolet light.<sup>317</sup>

### The Total Quantity of Blood

A variety of physiologic mechanisms operate to maintain blood volume within narrow limits. Therefore, in most clinical situations the total quantity of erythrocytes in the body tends to be closely related to their concen-

tration in the blood. There are, however, well-known clinical entities in which the blood volume may deviate considerably from normal. These include hemorrhage, dehydration, overhydration, congestive heart failure, renal disease, cirrhosis of the liver, and others. In these disorders the measures of concentration may not accurately reflect total quantity. Measurements of red cell volume, the plasma volume, or both may be necessary if the true clinical situation is to be assessed.

### Methods for Determination

The direct method of blood volume estimation was employed in 1854 by Welcker who bled animals to death, washed out the vessels with water, and extracted the hemoglobin still remaining in the tissues by mincing the organs and placing them in water for several days after the bile, intestinal contents, and urine had been removed.<sup>395</sup> Welcker concluded that the blood volume of mammals constitutes 7.7% of the body weight. This value was confirmed in man by Bischoff whose subjects were two condemned criminals.<sup>395</sup>

Most modern methods depend on the dilution principle. A substance is introduced into the circulation, and, after an appropriate interval for mixing, the space in which it is distributed is calculated from the degree to which it is diluted. Thus,

$$\text{Distribution space} = \frac{\text{amount injected}}{\text{concentration}}$$

If the substance is confined to the plasma, then the distribution space is equivalent to plasma volume; if confined to the erythrocytes, the distribution space becomes a measure of red cell volume.

With an ideal label, the distribution space would correspond precisely to the circulation volume to be measured, and excretion, destruction, or loss to tissues would be negligible, or at least could be quantitated. Furthermore, the label should mix quickly and completely with various parts of the circulation, and should be free of significant side effects. Finally, methods of measuring the

label should be accurate, convenient, and inexpensive.

Over the years, many different labels have been used in attempts to achieve these objectives. These include isotonic sodium chloride solutions,<sup>377</sup> tetanus antitoxin,<sup>372</sup> aca-cia,<sup>390,391</sup> and homologous precipitating anti-serum.<sup>379</sup> The use of carbon monoxide as a label for hemoglobin, introduced in 1882 and improved in recent years,<sup>373</sup> was shown to give significantly higher (16%) values than are obtained by other methods<sup>393</sup> because hemoglobin in bone marrow, muscles, and elsewhere, and other extravascular pigments, are tagged, in addition to the hemoglobin in the circulation. Subsequently, the introduction of the dye dilution method<sup>389</sup> provided a simple technique that could be applied widely. The introduction of radioactive elements in physiologic studies led to a geometric acceleration of investigations in this field. The first result was an accumulation of discordant values. Now, however, many of the problems involved in the measurement of blood volume are understood, even if not completely solved, and one can define precautions that must be taken, as well as the values that can be obtained under a variety of circumstances.<sup>384</sup>

**PLASMA VOLUME.** The introduction of the nontoxic, slowly diffusing blue dye, T-1824 ("Evans blue"), solved some of the problems presented by the original "brilliant vital red." The use of T-1824 involves the injection of a known quantity of dye and the subsequent withdrawal of samples of blood at appropriate intervals for determination of dye dilution. The dye is firmly bound to the plasma albumin<sup>385</sup> and therefore is diluted in the initial distribution space of albumin, which is approximately equivalent to the plasma volume.

Special precautions must be taken to determine the exact amount of dye injected and that present in the samples.<sup>384</sup> Methods have been devised for extraction of the dye, thus permitting greater accuracy in the measurement.<sup>373</sup> Graphic analysis of the time-concentration curve on a semi-log plot and

back extrapolation of the disappearance curve provide the accepted means of arriving at the value for the initial concentration of dye needed for calculating the plasma volume.

*Serum albumin* tagged with radioactive iodine ("RISA")<sup>378,384,388,397</sup> gives results comparable with the T-1824 method<sup>396</sup> and, because the half-life of <sup>131</sup>I is only eight days, determinations can be repeated at intervals. Apparatus has been designed to facilitate such repeated determinations (Volumetron).<sup>399</sup> The RISA method is subject to errors similar to those of the dye method but also has certain advantages.<sup>396</sup> It has been observed that albumin may be lost to the vascular bed early in the measuring process, and that this phenomenon is particularly striking in individuals who are ill as opposed to healthy subjects.<sup>398</sup> When albumin is lost in the vascular bed, the initial albumin space will be larger than the plasma volume. A method for compensating for this error has been developed.<sup>398</sup>

Another isotope, <sup>113m</sup>indium, may be useful for plasma volume determinations.<sup>400</sup> Indium binds firmly to transferrin (page 158), and the initial transferrin distribution space, like the albumin space, is roughly equivalent to the plasma volume. Values for plasma volume determined with indium were about 5% higher than those determined with RISA. Since <sup>113m</sup>indium has a short half-life (100 minutes), determinations may be repeated frequently; furthermore, the radiation dose is very low.

**RED CELL VOLUME.** The *Ashby technique* of differential agglutination of red cells (page 197) has been used for the estimation of red cell volume and can be performed with considerable accuracy and without special equipment; however, because the procedure is tedious and scrupulous care is required,<sup>371</sup> it is rarely used. Isotopic methods which include the use of <sup>59</sup>Fe, <sup>32</sup>P and <sup>51</sup>Cr are preferred.<sup>381</sup>

The *radioactive iron* method involves the administration of <sup>59</sup>Fe to a donor, to allow incorporation of the iron into his red corpuscles, and the subsequent transfusion of the

donor's blood into the subject.<sup>381,386</sup> The dilution of the transfused blood is then determined by measuring the radioactivity of the recipient's blood. This cumbersome method is now rarely used.

A simpler technique consists in the introduction of *radioactive phosphorus* ( $^{32}\text{P}$ ) into the erythrocytes *in vitro* and their subsequent return to the circulation, where their dilution is measured.<sup>375</sup> Thus, no problem of securing a donor and no concern regarding blood types arises. Many improvements on the original technique have been introduced.<sup>392</sup>

*Radioactive chromium* ( $^{51}\text{Cr}$ ) has become the most widely used label for measurement of red cell volume<sup>383,394</sup> because it is held more avidly by red cells than is radioactive phosphorus.<sup>394</sup> The amount commonly used is well below the safe radiation dosage for humans. Since there is no significant loss of  $^{51}\text{Cr}$  to the plasma for 24 hours or more, only one or two samples need be taken at whatever postinjection time is considered necessary for complete mixing in the circulation.

**TOTAL BLOOD VOLUME.** Methods are available whereby simultaneous measurements of plasma volume, by means of RISA, and of red cell volume, with  $^{51}\text{Cr}$ , can be made.<sup>380 382 387 401</sup> More often, the total blood volume is calculated from either the plasma volume or the red cell volume and a "corrected" value is determined for the VPRC. It has been shown that the "venous" hematocrit overestimates the proportion of red cells in the circulating blood as a whole, the so-called "body" hematocrit. The VPRC in the capillary bed is substantially lower than in venous blood so that the "body" hematocrit is approximately 91% of the VPRC in venous blood.<sup>376</sup> Under most conditions the ratio of "venous" to "body" hematocrit is a constant one,<sup>386</sup> so that a correction factor of 0.91 can be used. However, in patients with splenomegaly the body hematocrit/venous hematocrit ratio (BH/VH) is increased in direct proportion to the degree of splenic enlargement, because of the increased concentration of erythrocytes in the spleen.<sup>380</sup> In such patients, the increased concentration of

red cells in the spleen offsets the relatively low concentration in small blood vessels so that BH/VH is closer to 1.0 than to 0.91. In the presence of extravascular fluid retention, the ratio may similarly depart from the usual one in conditions of prolonged oligemic shock in which capillary blood flow is altered radically, as well as in patients with congestive cardiac failure.<sup>376</sup>

In addition, the VPRC must be corrected for plasma trapped in the red cell column (page 114).

### The Specific Gravity of Blood

The specific gravity of blood, that is, the ratio of the weight of the blood to the weight of the same volume of water at a temperature of 4° C, may be determined directly by weighing a measured volume of blood. Schmaltz<sup>434</sup> described a capillary pycnometer designed to make this determination. Such a method, however, is time-consuming, and various indirect methods for measuring specific gravity have been devised.<sup>426,427,428 430</sup>

The normal specific gravity of blood as determined by the pycnometric method is given as 1.048 to 1.066 with reported averages of 1.052 to 1.063. It is slightly higher in men (1.057) than in women (1.053). There is a normal diurnal variation of about 0.003, the specific gravity being generally lower in the afternoon and after meals and higher after exercise and during the night.<sup>433</sup> The specific gravity of the blood serum is 1.026 to 1.031, while that of the erythrocytes is 1.092 to 1.095.<sup>430</sup>

The specific gravity of the blood depends on a number of factors, particularly the quantity and hemoglobin content of the red corpuscles and the protein content of the plasma. Since these are usually measured independently, few have been interested in studying the specific gravity of blood in various disease conditions.<sup>433,435,436</sup>

The *copper sulfate method*<sup>431</sup> for measuring specific gravity has a number of advantages as compared with the methods previously used. No precision instruments are required.

The procedure consists in letting drops of plasma or whole blood fall into a graded series of solutions of copper sulfate of known specific gravity and noting whether the drops rise or fall in the solutions. Each drop on entering the solution becomes encased in a sack of copper proteinate and remains as a discrete drop without change of gravity for 15 or 20 seconds, during which its rise or fall reveals its gravity relative to that of the solution. The method is capable of measuring gravities to  $\pm 0.00005$ , the degree of accuracy depending on the number of standard copper sulfate solutions used.

The copper sulfate method still enjoys some popularity as an indirect way of detecting anemia in situations requiring mass screening, for example, of potential blood donors. Under these circumstances, usually only one or two copper sulfate solutions are used, with a specific gravity of 1.055 for men and 1.053 for women. Donors are considered suitable if their blood specific gravity exceeds that of the standard solution.

The microhematocrit method of determining the VPRC (page 113) and electronic methods of measuring "hematocrit"<sup>429</sup> are nearly as rapid as the copper sulfate screening method. Furthermore, in these methods, in addition to deviation from normal, the degree of anemia is estimated. As a result, the copper sulfate method may soon become obsolete in laboratory settings. It has special advantages under battlefield conditions, however, because no power source is required.

### The Blood Viscosity

The simplest method for the measurement of the blood viscosity is by means of a capillary viscosimeter.<sup>437</sup> The instrument is based on Poiseuille's law, namely, that the flow rate of fluids in capillaries of equal caliber, under the same pressure and at the same temperature, depends upon the inner friction (viscosity). In the viscosimeter, blood and, in another tube, distilled water are drawn under equal pressure through capillary tubes, of equal caliber and length, into graduated tubes. The blood is forced to reach a certain

point. The volume of distilled water that has been drawn up under this pressure is indicated by the graduated tube containing the water. Since volume is inversely proportional to viscosity, the reading on the water tube indicates the viscosity of the blood in relation to that of distilled water. The test requires only one drop of blood and may be carried out in 30 seconds.

The relative viscosity of the blood of healthy adults ranges from 3.5 to 5.4 (average 4.5). That of serum is 1.4 to 1.8; values for plasma are about 20% higher.

The viscosity of blood as measured in capillary viscosimeters is not the same as it is within the vasculature.<sup>446</sup> Blood is not a Newtonian fluid and, therefore, does not obey Poiseuille's law. As a result, blood viscosity will have many different values in different parts of the vascular system. In general, within vessels such as the ascending aorta, where the "shear rate" (a function of vessel diameter and flow rate) is relatively great, viscosity will be low; increasing values are expected as vessel size and flow rate decrease. An exception to this generalization exists with respect to capillaries, in which vessel diameter is only slightly greater than cell size. The viscosity, under such circumstances, is related only to plasma viscosity, rather than to whole blood viscosity.<sup>446</sup>

At a given shear rate, blood viscosity is related to the composition of the blood, especially the quantity of erythrocytes, the concentration of macroglobulins, and, in some instances, the number of leukocytes. The influence of the VPRC on viscosity for two different vessel sizes is shown in Figure 3-25. In general, there is a sharp increase in viscosity with increases in VPRC above the normal range.

The influence of macroglobulins on blood viscosity is indicated in Figure 3-26.<sup>440</sup> Although levels of most of the other immunoglobulins have only modest effects on viscosity, those belonging to the class IgG<sub>3</sub> polymerize readily and lead to changes similar to those found in macroglobulinemia.<sup>439</sup> Symptoms of increased blood viscosity due to macroglobulinemia include a tendency to

Fig 3-25 Relation of VPRC (hematocrit) to blood viscosity in centipoise (cp) as measured in a capillary viscosimeter compared with that calculated for shear rates of 120 sec<sup>-1</sup> (ascending aorta) and 12 sec<sup>-1</sup> (medium arteriole) (From Wells and Merrill<sup>440</sup> courtesy of the authors and American Journal of Medicine)

Fig 3-26 Relation of macroglobulin (IgM) and IgG concentrations to viscosity (From Fahey et al<sup>440</sup> courtesy of the authors and the Journal of the American Medical Association)

bleed from the nose and gums, ocular disorders, and neurologic signs.<sup>439,440</sup> In polycythemia, similar symptoms may also be related to excessively viscous blood.

The quantity of leukocytes is of significance only when they are greatly increased in number. This is true particularly in myelocytic leukemia because the myeloid leukocytes are larger than lymphocytes. The increased blood viscosity in leukemia is probably responsible for some of the symptoms of this disease, such as dizziness, roaring sensations in the ears, and perhaps even priapism. Stephens<sup>444</sup> observed relative blood viscosities greater than 9 in patients with chronic myelocytic leukemia and demonstrated that blood circulation time was greatly delayed. The influence of blood platelets on viscosity is not clear.<sup>441</sup>

An increase of carbon dioxide in the blood is said to increase viscosity through changes in osmotic relationships. Venous blood has been found to possess a higher viscosity than arterial blood.

Naegeli<sup>443</sup> considered viscosimetry to be an important adjunct in routine blood examinations in the sense that a change in many factors is at once reflected by alterations in blood viscosity. In Naegeli's clinic, charts were devised whereby, from the viscosity of the plasma and whole blood, the protein content of the plasma and the volume of packed red cells could be calculated. Viscosimetry received considerable attention in European clinics but has attracted only limited attention in the United States.<sup>448</sup>

### Suspension Stability of the Blood—The Sedimentation Test

The blood is essentially a suspension of corpuscles in plasma. In 1918, Fahraeus,<sup>462</sup> while seeking an early test for pregnancy, discovered that the suspension stability of the blood is altered in pregnancy, but he found that the speed of sedimentation is also accelerated in many diseases. A test was thus discovered which, because of its simplicity and its wide applicability, soon became very popular.

Variations in the suspension stability of the blood probably led to the development of the theory of the four humors of the ancient Greeks. When blood is withdrawn from a healthy person, it clots quickly and two portions, the clot and the serum, are formed. In the presence of disease, sedimentation of the red corpuscles may be so accelerated that some of the corpuscles quickly settle to the bottom of the vessel in which the blood has been collected and, since they are deprived of oxygen, appear very dark. Above this, the corpuscles still containing oxyhemoglobin, and therefore appearing red, will be found. The rapid sedimentation of the erythrocytes permits some separation of the leukocytes and these, especially when there is leukocytosis, form, together with fibrin, a well-defined grayish-white layer in the uppermost portions of the clot. These three portions of the blood were named respectively, "melancholia" or "black bile," "sanguis" or "true blood," and "phlegma" or "mucus." The blood serum itself formed the fourth humor, "cholera" or "yellow bile." Ill health was attributed to the failure of the four humors to mix. Not until the time of Paracelsus, it seems, was it considered possible that this separation into several layers might be the result, rather than the cause, of disease. The grayish-white layer of fibrin and leukocytes continued for centuries to occupy the attention of physicians, being referred to as "crusta inflammatoria," "buffy coat," or "size." Venesection was practiced in order to rid the body of this supposedly noxious substance.

### The Nature of the Sedimentation Phenomenon

The rate of erythrocyte sedimentation depends upon the interaction between opposing physical forces (Fig. 3-27). Settling occurs because the density of the red corpuscles is greater than the density of the medium. The fall of the red corpuscles causes an upward displacement of the medium, thus producing an upward current and a retarding force. In blood drawn from normal persons

Fig 3-27. The effect of certain factors on sedimentation rate. Arrows pointing downwards represent the downward force of the red corpuscles (DF). Arrows pointing upwards represent the retarding effect (RF) of the medium and the limitation produced by the end of the tube.

Normal blood  $RF \text{ almost} = DF$

Anemia  $RF < DF$

Less retardation from displacement of plasma by red corpuscles

Inclined tube  $RF < DF$  Plasma streams along upper side of tube under the glass, exerting no retarding effect

Increased rouleau formation  $RF < DF$  because  $RF$  depends on relative surface. The larger the volume, the smaller the relative surface.

the concentration of the red corpuscles is relatively great, and a relatively large volume of plasma must be displaced upward if much sedimentation is to occur. Actually the downward and upward forces in normal blood are nearly equal and consequently little settling occurs.

When the number of red corpuscles is less than normal, there is less retardation of sedimentation by the red corpuscles themselves. No matter how high the column of blood may be, its length is not infinite and retardation is produced by the cells striking the bottom and piling up on one another. Obviously, the fewer the cells the less this effect will be. Methods have been described for "correcting" for the effect of anemia.<sup>477,483</sup> These are discussed more fully below.

The statements that have been made refer to a column of blood that stands in the vertical position. Any deviation from the vertical causes an acceleration in the rate of sedimentation. This occurs because the plasma streams along the upper side of the tube from

which the red corpuscles have already settled out and the red corpuscles therefore encounter less hindrance from displacement of the medium.

The factor that is of chief importance in affecting the sedimentation rate in disease is the size of the sedimenting particle. The larger the volume of the particle, the smaller is the relative surface. The upward or retarding force is a function of the surface area exposed to the medium. The downward force depends on the weight of the particle. In the presence of certain conditions the aggregation of the red corpuscles (rouleaux formation) is greatly increased, and this results in the production of corpuscular aggregates of large volume but relatively small surface area. This phenomenon is the chief cause of the acceleration of sedimentation rate encountered in the presence of disease and in pregnancy.

The reason for the increased aggregation is not entirely clear; however, it probably results from changes in the negative surface charge (zeta potential) of the red corpuscles.

This charge, a function of the sialic acid groups on the cell membrane (page 100), can be attenuated by the dielectric effect of proteins in the surrounding plasma, especially asymmetric macromolecules like fibrinogen and gamma globulin.<sup>455</sup> Thus, alterations in sedimentation rate generally reflect alteration in these plasma proteins. Indeed, the addition of fibrinogen leads to a greatly increased sedimentation rate,<sup>467</sup> and the fact that the plasma fibrinogen is usually increased when the sedimentation rate is accelerated led to the conclusion that increased sedimentation velocity usually is the result of an increase in the quantity of fibrinogen in the plasma.<sup>465,473</sup> The addition of other protein fractions to blood also leads to an acceleration of sedimentation,<sup>462</sup> but the effect is less marked than that produced by the addition of fibrinogen. Close correlation between plasma globulin and sedimentation rate has been observed,<sup>452,467</sup> particularly with plasma proteins of high molecular weight, such as the  $\alpha_2$ - and  $\gamma_1$ -macroglobulins.<sup>470</sup> Much less commonly, an increase in sedimentation rate may be the result of erythrocyte factors.<sup>468,480</sup>

A method for measuring the sedimentation rate was devised in 1924 by Westergren,<sup>481</sup> and continues to be popular. It requires a special tube 30 cm in length, open at both ends, and a rack to fix the tubes in a vertical position during sedimentation. Also widely used is a method in which sedimentation is measured in the Wintrobe hematocrit.<sup>483</sup> With both methods, results are expressed in millimeters per hour (for normal values, see Appendix A). The results with the two methods do not always correspond, chiefly because the Westergren tube is longer, and sedimentation in it is less retarded by packing of cells. The Wintrobe method has the important advantage of allowing the subsequent determination of the VPRC, the volume of packed leukocytes and platelets, and the icterus index in the same tube and with the same volume of blood used for the sedimentation rate. It is often preferred for these reasons.

A number of technical variations have been introduced,<sup>463</sup> including micro methods,

<sup>460,472,478</sup> sedimentation at an angle of 45 degrees to accelerate the process,<sup>457,479</sup> and improvements in the Westergren method.<sup>461,464</sup> Most sophisticated of the improved methods is the "zeta sedimentation ratio" (ZSR), a measure of the degree of packing of erythrocytes occurring during four, 45-second cycles of dispersion and compaction in special capillary tubes.<sup>455</sup> This measure is linearly related to increases in fibrinogen or gamma globulin, can be performed on micro quantities, and is not affected by anemia. It is faster than either the Westergren or Wintrobe methods, but requires a special instrument, the Zetafuge.

The values are not expressed in millimeters per hour but as ml/dl (vol %) and the normal range is 40 to 51 ml/dl in both males and females.

With either the Wintrobe or Westergren technique, values are affected by the VPRC,<sup>460,483</sup> and various methods for "correction" for anemia have been devised.<sup>453,469,483</sup> Such corrections do not apply to all forms of anemia, however, because differences in the size<sup>475</sup> and hemoglobin content<sup>476</sup> of the red cells also affect the sedimentation rate. Furthermore, anisocytosis may interfere with rouleau formation, and poikilocytosis such as that encountered in sickle cell anemia actually prevents the formation of rouleaux. In sickle cell anemia, sedimentation is very slow even when there is marked anemia.<sup>456</sup> An important objection to correction for anemia is the fact that all methods of correction are only approximate and are also artificial. Furthermore, many who use such corrections do not recognize their artificiality and tend to make more of this ultra-refinement than it merits. It seems best, therefore, to abandon correction of sedimentation rate for anemia; however, it is wise to record simultaneously the VPRC, thereby giving an indication of the presence or absence of anemia and its degree.

### Variations in Disease

The sedimentation test is a nonspecific reaction which may be compared with the body temperature, the pulse rate, and the

leukocyte count, in that it gives information of a general character. It is a measure of the presence and intensity of morbid processes within the body. The test is a useful supplement to clinical methods because it may be accelerated when the temperature, pulse, and even the leukocyte count are normal, particularly in chronic disorders and in localized inflammatory diseases.

In general, sedimentation rate is increased in all acute general infections while, in localized acute inflammatory conditions, variations in sedimentation rate depend on the nature and severity of the morbid process. Thus, in localized acute suppurations, such as pelvic inflammatory disease, there may be a pronounced acceleration even when the pulse rate and temperature are normal. Again, in chronic localized infections the rate varies with the extent and nature of the infection. Uncomplicated neoplasms are not necessarily associated with rapid sedimentation even when malignant.<sup>474</sup> If the neoplasm is malignant, sedimentation tends to be accelerated when the tumor is very vascular, when there is a tendency to break down, or when there is much reaction about the tumor.<sup>471</sup>

It has been reported that an increased sedimentation rate due to inflammation can be distinguished from that due to neoplastic disease. The method consists of performing the test before and after incubation of the plasma for four hours at 37° C. Such incubation is said to reduce the sedimentation rate considerably less in neoplastic disease than in inflammatory disease.<sup>466</sup>

One of the most important uses of the sedimentation test is in calling attention to the presence of more or less occult disease and for this reason it is as valuable a routine procedure in examination as is urinalysis or the estimation of blood pressure. Not infrequently the sedimentation rate may be accelerated when clinical and other laboratory studies yield negative results. If technical error can be ruled out, such a finding should be considered a challenge to the acumen of the physician, and a diligent search must be made for its cause. One cannot insist that an accelerated sedimentation rate always indi-

cates the presence of pregnancy or disease,<sup>451</sup> especially in elderly patients.<sup>451</sup> However, in clinical practice it may well be regarded as a sign of disease until the physician is thoroughly satisfied that the patient is perfectly well. On the other hand, a normal sedimentation rate does not necessarily mean that all is well. Normal rates occasionally have been found in patients with neoplastic conditions of the liver, cirrhosis,<sup>458</sup> chronic passive congestion, cachexia, or other serious disease.<sup>482</sup>

As an aid in differential diagnosis, the sedimentation test may be useful. Other things being equal, an accelerated rate suggests organic disease rather than a functional disorder.

Serial measurements of the sedimentation rate may serve as a guide to the progress of disease that has already been recognized. This is particularly true in regard to pulmonary tuberculosis,<sup>459</sup> rheumatic carditis,<sup>438</sup> rheumatoid arthritis, and certain malignancies, including Hodgkin's disease.

## *Production of Erythrocytes*

### **Nutritional Requirements for Red Cell Production**

- Protein and Amino Acids
- Vitamins
- Minerals
- Iron Metabolism
  - Total Body Iron
  - Iron Balance
  - The Iron Cycle
- Hemoglobin Structure and Synthesis
  - Heme
  - Globin
- Control of Erythropoiesis
  - Tissue Oxygen
  - Erythropoietin
  - Role of the Nervous System
  - Other Erythropoietic Substances

### **Nutritional Requirements for Red Cell Production**

From what is known about the composition of the red cell, it is apparent that a great variety of materials is required for erythropoiesis. None of these is unique in the sense that it is needed for erythropoiesis alone and not for other systems of the body as well. Anemia is a late sign of nutritional deficiency. The effects of deficiency develop insidiously and are widespread, but most other tissues are less readily available for examination than are the cells of the blood. Consequently, examination of the blood constitutes an important means for the detection of nutritional

deficiency. In addition, in relation to certain essential substances a system of priorities seems to operate, resulting in deprivation of the erythropoietic system before functional disturbances in other tissues are detected. Thus, when iron is in limited supply, hemoglobin production is impaired before deficiencies in certain other iron enzymes are detectable (page 659).

For consideration in this section are those nutrients for which requirement is so critical that their lack results in detectable changes in the blood. Lack of the many other required substances results in critical changes in other tissues long before the hematopoietic system is seriously affected.

### **Protein and Amino Acids**

Knowledge concerning the substances needed for hematopoiesis was first gained by observing the effects of dietary restrictions. Whipple and his associates pioneered in the field by showing clearly the importance of protein in erythropoiesis.<sup>10,17</sup>

Dietary deprivation of protein leads to anemia in a variety of experimental animals, including pigs,<sup>4</sup> rats,<sup>10</sup> and monkeys.<sup>7,11</sup> The anemia appears to result chiefly from impaired erythrocyte production since reduced circulating reticulocytes, reduced iron utilization by the red cell, and erythroid hypoplasia of the marrow are observed. However, there may also be a reduction in the red cells' life span, perhaps because of structural defects in these cells.<sup>6</sup>

That protein deficiency in man leads to anemia may be inferred from observations of prisoners of war<sup>8,15</sup> and patients with kwashiorkor, a syndrome of severe protein-calorie malnutrition.<sup>1,7,11,12</sup> The anemia in kwashiorkor is complex since there may be deficiencies in many nutrients besides protein, as well as complicating infections. Nevertheless, in most instances the anemia has responded to administration of protein in the form of cow's milk without other added nutrients.<sup>1,11</sup>

In rats, the anemia of protein deficiency can be prevented or alleviated by the administration of erythropoietin.<sup>10</sup> This observation suggests that the anemia of protein deprivation does not result from a fundamental lack of hemoglobin substrates at the oörmoblast level. Instead, when the organism is confronted with a limited supply of amino acids, the erythropoietin control mechanism is altered. This results in a diversion of amino acids to the synthesis of other proteins, perhaps ones that are more urgently needed.

With more severe or prolonged protein starvation, it is possible that other mechanisms play a role in the development of anemia, such as diminished production of hormones, especially thyroxine, adrenocorticoids, and testosterone.<sup>2</sup>

All of the ten "essential" amino acids are required for hematopoiesis in the rat. In the order of decreasing importance these are: histidine, valine, leucine, isoleucine, lysine, arginine, methionine, tryptophan, phenylalanine, and threonine.<sup>13</sup> Glycine also is required. Peptides are used less efficiently than are simple amino acids. In dogs made anemic by repeated bleeding, proline, threonine, glutamic acid, cystine, aspartic acid, histidine, glycine, phenylalanine, methionine, tryptophan, leucine, tyrosine, lysine, valine, isoleucine, alanine, arginine, and hydroxyproline, when given in amounts of 1 to 2 g daily, were found to be effective, in decreasing degree, in producing 34 to 10 g hemoglobin over a two-week period.<sup>17</sup>

The specific role of each amino acid in blood formation is yet to be determined. There is no correlation between the quantity

of an amino acid found in globin (page 174) and its effectiveness in hemoglobin regeneration.<sup>3</sup> The feeding of a diet containing acid hydrolyzed casein results in the development of a moderate anemia in rats and severe normocytic or slightly microcytic anemia, without hypochromia, in swine.<sup>5</sup> These anemias are accompanied by leukopenia, hypoplastic or normal bone marrow, and a normal serum iron level and are in all likelihood due to tryptophan deficiency. The severe anemia that develops in rats maintained on deaminized casein appears to be due to the effects of hexahomoserine, which acts as a lysine antagonist.<sup>9</sup>

## Vitamins

### Vitamin B<sub>12</sub> and Folic Acid

The standard salmon-bread ration that Whipple and coworkers fed dogs made anemic by bleeding<sup>17</sup> was deficient in a number of respects. No doubt some of the beneficial effects of the foods tested in their experiments were due to the iron and the vitamins that were contained therein. The anemia, leukopenia, and granulocytopenia produced experimentally in monkeys by feeding them a diet comparable to that taken by natives in India,<sup>179</sup> as well as the "tropical macrocytic anemia" of these natives, were cured by giving autolyzed yeast, a recognized source of "vitamin B." Brewer's yeast was also shown to be effective in the treatment of pernicious anemia if given in large quantities,<sup>180</sup> a response that subsequently was recognized to be due to the yeast's folate content. With the isolation of vitamin B<sub>12</sub> from liver<sup>146,158</sup> it could be demonstrated that this substance is the same as the "extrinsic factor" that Castle postulated as requiring "intrinsic factor" for its absorption (page 138), and that it is also identical with the "antipernicious anemia principle" that was thought to be formed through the interaction of the "intrinsic" and "extrinsic" factors. It was thus indicated that deficiencies of vitamin B<sub>12</sub> and of folic acid are involved in the development of megaloblastic anemia in man.

Fig 4-1. Structure of cyanocobalamin, the official form of vitamin B<sub>12</sub>. There are six primary amide groups and one secondary amide joining the aminopropanol residue to the propionic acid group in ring D. Cyanocobalamin is formulated as a diester of phosphoric acid, the free acid group of the phosphate being neutralized by a positive charge on the cobalt atom. The coenzyme B<sub>12</sub> differs from the vitamin mainly in the absence of cyanide and the presence of an adenine nucleoside. (From Barker et al.<sup>24</sup> courtesy of the authors and the Journal of Biological Chemistry.)

### Vitamin B<sub>12</sub>

Vitamin B<sub>12</sub> is an unusual porphyrin<sup>24</sup>; two of its four pyrrole rings are linked directly rather than being joined by methene bridges, as are the other rings in the molecule and in other porphyrins. Figure 4-1 shows the structure of cyanocobalamin and indicates how the porphyrin structure is linked to the ribonucleoside of 5,6-dimethylbenzimidazole by a phosphate ester bond and by coordination of one of the nitrogens of the imidazole ring to the cobalt. Cobalt is in the position occupied by iron in the heme molecule and cyanide fills the unsatisfied valence of the

cobalt. The discovery of cobalt as a component of vitamin B<sub>12</sub> represented the first time that this mineral had been found in a pure substance of biologic origin. Vitamin B<sub>12</sub> was first isolated in 1948, but laboratory synthesis of this complex substance was not accomplished until 1973, after 11 years of work by R. B. Woodward and a team of 99 coworkers.<sup>121</sup>

Cyanocobalamin is largely an artifact of isolation procedures, the cyanide coming probably from the charcoal used. It was the first active cobalamin isolated because it is the most stable of a series of compounds. Other cobalamins differ from cyanocobalamin in the

nature of the ligand attached to the cobalt atom in the place of CN<sup>-</sup>, eg, OH<sup>-</sup> (hydroxocobalamin, vitamin B<sub>12a</sub>),<sup>72</sup> H<sub>2</sub>O (aquocobalamin, vitamin B<sub>12b</sub>), ONO<sup>-</sup> (nitrocobalamin, vitamin B<sub>12c</sub>).

Although all of the above cobalamins exhibit the nutritional properties of vitamin B<sub>12</sub>, they represent neither the naturally occurring nor the biochemically active (coenzyme) forms of the vitamin. Two vitamin B<sub>12</sub> coenzymes have been identified, namely, methyl cobalamin and 5'-deoxyadenosyl cobalamin. Both are unstable, are decomposed on exposure to light, and are easily converted to one of the other, more stable cobalamins. In liver, 70% of the vitamin B<sub>12</sub> is in the 5'-deoxyadenosyl form, and part, perhaps all, of the remainder is in the methyl form.<sup>163</sup>

**SOURCES AND REQUIREMENTS.** Vitamin B<sub>12</sub>, unlike other B vitamins, is not synthesized by higher plants but is produced by many bacteria and certain molds. As a consequence, it is found in soil and water, and in the intestines or rumina of some animals. From these sources it reaches animal tissues such as liver, glandular tissues, muscle, eggs, and, in lower concentration, cheese and milk.<sup>108</sup>

Since animal protein foods tend to be relatively expensive, the amount of vitamin B<sub>12</sub> in the diet is related to cost. The average "high-cost" diet contains 20 µg per day of vitamin B<sub>12</sub>, whereas a "poor diet" (1000 calories and 32 g of protein a day) contains about 3 µg.<sup>50</sup> Consumption of a diet with still lower amounts of vitamin B<sub>12</sub> requires avoidance not only of meat, but also of eggs and milk. In Europe and the United States, unusually strict vegetarians (vegans) are the only group known to consume such a diet.

As little as 0.1 µg of vitamin B<sub>12</sub> per day will produce a minimal hematopoietic response when given parenterally to patients with uncomplicated pernicious anemia in relapse.<sup>166</sup> This amount is so small that only such poisons as plutonium and botulinus toxin are known to be physiologically active in any smaller quantities. It has been estimated that the minimal daily adult requirement for the vitamin is 0.6 to 1.2 µg/day.<sup>93</sup>

This amount will prevent all signs and symptoms of deficiency and will maintain serum vitamin levels within normal limits. However, a somewhat greater intake (3 to 10 µg/day) might be necessary to maintain stores of the vitamin within normal limits.

Vitamin B<sub>12</sub> is an exceptionally well-stored vitamin. The total body content in normal persons has been estimated at 5000 µg (approximate range: 3500 to 11,000 µg).<sup>81</sup> The liver is the principal storage depot; it contains about 1700 µg (750 to 3000 µg), smaller amounts being distributed in other tissues. Loss of vitamin B<sub>12</sub> from the body occurs at a rate of 0.05 to 0.2% per day.<sup>21,81</sup> Thus, in a normal subject, 2.5 to 10 µg are lost per day and must be replaced if stores are to be maintained.

**ABSORPTION.** Normal absorption of vitamin B<sub>12</sub> requires that it be bound to a protein in gastric juice called "intrinsic factor." When so bound, about 70% of dietary vitamin B<sub>12</sub> is absorbed. When unbound, less than 2% is absorbed. *Intrinsic factor*<sup>73,90</sup> (IF) is an alkaline-stable, thermolabile glycoprotein; it is sensitive to peptic digestion and to storage at acid pH, especially when not bound to vitamin B<sub>12</sub> prior to digestion.<sup>20</sup> It binds B<sub>12</sub> and its analogues with a high affinity. The molecular weight of IF as a monomer is 50,000 to 60,000. In the presence of vitamin B<sub>12</sub>, two molecules of the monomer combine rapidly to form a dimer that binds two molecules of the vitamin, the complex having a molecular weight of about 115,000.<sup>92</sup>

In the hog, IF is formed in the pyloric and Brunner glands of the duodenum, but in man it is thought to be derived from the parietal cells of the fundus and body of the stomach.<sup>64,73,98</sup> Its secretion in normal persons is augmented by histamine, betazole hydrochloride and methacholine,<sup>100</sup> as well as by gastrin.<sup>171</sup> Intrinsic factor appears to be of greatest importance in omnivores. Carnivores, such as dogs,<sup>137</sup> lack the protein.

Although most nutrients are absorbed mainly in the upper segments of the small intestine, vitamin B<sub>12</sub> is absorbed principally from the lowest level of the ileum.<sup>138,151</sup> The

absorptive cells of the ileum are highly specific for this function; if they are transposed surgically to the region of the upper jejunum, they retain their capacity to absorb vitamin B<sub>12</sub>.<sup>58</sup> Upon reaching the ileum, the intrinsic factor-B<sub>12</sub> complex becomes attached to specific receptor sites on the brush border of the mucosal cells,<sup>56</sup> a process requiring a pH greater than 5.7 and the presence of divalent cations, especially calcium.<sup>60</sup> Little is known about the steps occurring between the time of attachment at the ileal receptor sites and the appearance of vitamin B<sub>12</sub> in the plasma. It is probable that the vitamin enters the absorptive cell and that the intrinsic factor remains outside.<sup>52,95</sup> Following absorption, the vitamin is associated for several hours with the mitochondrial fraction of the mucosal cells,<sup>142</sup> but the significance of this localization is not known.

Optimal absorption of vitamin B<sub>12</sub> requires pancreatic secretions. In a proportion of human subjects with pancreatic insufficiency,<sup>168</sup> as well as in partially pancreatectomized rats,<sup>169</sup> absorption of vitamin B<sub>12</sub> was found to be reduced. In both, the defect could be corrected by administration of pancreatic extracts. The mechanism of action of pancre-

atic secretions has not been established; it has been suggested that they either alter the vitamin B<sub>12</sub>-intrinsic factor complex to an absorbable form or destroy an inhibitor of absorption, such as a non-IF-protein vitamin B<sub>12</sub> binder.<sup>169</sup>

**TRANSPORT.** Most of the vitamin B<sub>12</sub> found in the circulation is bound to one of two proteins. These are designated transcobalamin I (TC I) and transcobalamin II (TC II).<sup>80</sup> Various chemical and physiologic characteristics of these two proteins are given in Table 4-I. Evidence for a third serum binder has also been reported.<sup>33,42</sup> It may be of leukocyte origin and accounts for the increase in unsaturated vitamin B<sub>12</sub>-binding capacity associated with leukocytosis.<sup>42</sup> It also is found in normal persons,<sup>33</sup> but its physiologic significance remains unknown.

Transport of vitamin B<sub>12</sub> is accomplished chiefly by transcobalamin II. This conclusion may be drawn from the following observations: (1) TC II binds nearly all of the newly absorbed or injected vitamin B<sub>12</sub>; (2) turnover of TC II-bound vitamin B<sub>12</sub> is relatively rapid<sup>96</sup>; (3) transfer of vitamin B<sub>12</sub> from TC II to tissues occurs rapidly in vivo and in

Table 4-1. Comparison of Two Plasma B<sub>12</sub>-Binding Proteins

	Transcobalamin I	Transcobalamin II
Molecular weight	115 000 <sup>75</sup> 121,000 <sup>100</sup>	36 000 <sup>75 100</sup>
Chemical nature	Glycoprotein <sup>75</sup>	
Electrophoretic mobility	$\alpha_2$ <sup>80</sup>	$\alpha_2/\beta$ <sup>80</sup>
Source	(?) Leukocytes <sup>49 51</sup>	(?) Liver <sup>105</sup>
Half life of bound vitamin B <sub>12</sub>	9-10 days <sup>99</sup>	1.5 hours <sup>99</sup>
Transfer to cells	Poor <sup>43 145</sup>	Rapid <sup>43 145</sup>
Manifestations of hereditary deficiency	Decreased serum B <sub>12</sub> levels, no anemia <sup>42</sup>	Growth failure, megaloblastic anemia <sup>79</sup>
Increased in	Chronic myelocytic leukemia, polycythemia vera <sup>88</sup>	Pregnancy <sup>88</sup>
Probable function	Storage	Transport

vitro<sup>63,143,145</sup>; and (4) vitamin B<sub>12</sub> metabolism is seriously impaired when there is hereditary lack of TC II.<sup>79</sup>

Transcobalamin I and the third serum binder appear to be related to other B<sub>12</sub>-binding proteins found in tissues and body fluids and secretions.<sup>42,75</sup> These so-called "R" proteins are immunologically similar, but apparently differ from one another in the amount of attached sialic acid.<sup>75</sup> The R protein in gastric juice accounts for the observed binding capacity of gastric juice in excess of that accounted for by intrinsic factor. Vitamin B<sub>12</sub> bound to transcobalamin I accounts for the major fraction of vitamin B<sub>12</sub> found in plasma; however, this fraction turns over relatively slowly. It has been suggested that TC I serves a storage, rather than a transport, function.

Microbiologic assay of serum using *Euglena gracilis* as the test organism has yielded widely varying values for normal adults in different laboratories, with mean concentrations ranging from 212 to 640 ng/l.<sup>24</sup> With improved methodology, a mean of 472 ng/l was found, with a range of 163 to 925. These figures are similar to those reported in *L. leichmannii* assays.<sup>101</sup> When measured by radioisotope dilution methods, values of 200 to 900 ng/l were thought to represent the normal range.<sup>113</sup> In vitamin B<sub>12</sub> deficiency due to pernicious anemia in relapse, levels of 9 to 113 ng/l were found.<sup>21</sup> Serial studies indicated that the bone marrow became megaloblastic when the serum vitamin B<sub>12</sub> concentration fell between 70 and 154 ng/l, at which time the total content of vitamin B<sub>12</sub> in the body was 100 to 660 µg.<sup>22</sup> Serum values below 100 ng/l are considered to be definitely subnormal and occur in association with a variety of megaloblastic anemias as well as with subacute combined degeneration of the spinal cord (page 612).

**FUNCTIONS.** A number of enzymatic reactions in microorganisms require vitamin B<sub>12</sub> coenzymes as cofactors.<sup>157,162</sup> In general, these reactions fall into two groups: those dependent on 5'-deoxyadenosyl cobalamin and those dependent on methyl cobalamin. The former usually involve intramolecular

exchanges of a hydrogen attached to one carbon atom with a group attached to an adjacent carbon atom; the latter involve transfer of methyl groups between molecules.

In mammalian tissues, only two vitamin B<sub>12</sub>-dependent reactions have been identified with certainty. The first of these is the synthesis of the amino acid methionine from homocysteine, a reaction of special interest because it requires not only methyl cobalamin but also a folate coenzyme, N<sup>5</sup>-methyl tetrahydrofolate (N<sup>5</sup>-methyl-FH<sub>4</sub>):

The second is a step in the catabolism of propionate; namely, the conversion of methylmalonyl coenzyme A (CoA) to succinyl CoA:

The relations of the coenzyme functions of vitamin B<sub>12</sub> to the metabolic consequences of B<sub>12</sub> deficiency have not been established. It is clear that there are two principal abnormalities in animals deficient in vitamin B<sub>12</sub>: defective deoxyribonucleic acid (DNA) synthesis and defective synthesis of myelin.

Two possible roles for vitamin B<sub>12</sub> in DNA synthesis have been suggested. The most likely is the so-called "methyltetrahydrofolate trap" hypothesis.<sup>127,136,177</sup> This holds that impaired DNA synthesis in vitamin B<sub>12</sub> deficiency is secondary to deranged folate metabolism. As a consequence of impaired conversion of homocysteine to methionine (see reaction above), N<sup>5</sup>-methyl tetrahydrofolate cannot be efficiently converted to tetrahydrofolate. As a result, folate becomes "trapped" in the N<sup>5</sup>-methyl form and a deficiency develops of N<sup>5</sup>N<sup>10</sup>-methylene FH<sub>4</sub>, the folate coenzyme required for thymidyllic acid synthesis (Fig. 4-3). Evidence for and against the hypothesis has been reviewed.<sup>78,136</sup> The second proposed role for vitamin B<sub>12</sub> in DNA synthesis is in the conversion of ribonucleotides to deoxyribonucleotides (the ribonucleotide reductase reaction).<sup>30</sup> In one microorganism, *L.*

*leishmannii*, this reaction requires 5'-deoxy-adenosyl vitamin B<sub>12</sub>, whereas in another, *E. coli*, it does not. Most of the reported observations suggest that human and mammalian ribonucleotide reduction, like the *E. coli* system, is not vitamin B<sub>12</sub> dependent.<sup>157</sup>

The biochemical reactions relating vitamin B<sub>12</sub> to myelin synthesis remain uncertain. In contrast to the lesions of defective DNA synthesis, the neurologic lesions of B<sub>12</sub> deficiency cannot be relieved by folate administration; therefore, a reaction unrelated to folate metabolism is presumed to be impaired. Since the only such reaction specifically identified in man is the methylmalonyl CoA mutase reaction, efforts to attribute the neurologic abnormalities in B<sub>12</sub> deficiency to a defect in this reaction have been made.<sup>70</sup> Relevant to this hypothesis is the observation that glial

cells grown in vitamin B<sub>12</sub>-deficient tissue cultures synthesized unusual 15- and 17-carbon fatty acids.<sup>26</sup> This abnormality was ascribed to accumulation of propionyl CoA. It was suggested that the incorporation of such fatty acids into myelin might account in some way for impaired neural function.

### Folic Acid

The term "folic acid" has been used both to designate a specific chemical compound, pteroylglutamic acid, and as a general term for related compounds with similar nutritional activity. The less specific term "folate" is to be preferred for the latter meaning. The pteroylglutamic acid molecule consists of three parts: pteridine, p-aminobenzoic acid, and glutamic acid (Fig. 4-2). Most of the

BROKEN LINES OUTLINE THE BASIC 1-CARBON ACCEPTOR (5,6,7,8-TETRAHYDROFOLIC ACID) (THFA) (FH<sub>4</sub>), AND THE VARIOUS 1-CARBON-DONATING COENZYMES DERIVED FROM IT.

Fig. 4-2. The folic acid molecule. Area enclosed by broken lines is the active center in one-carbon transfers. The four N atoms are added at positions 5, 6, 7 and 8 in tetrahydrofolic acid (FH<sub>4</sub>). Various one-carbon moieties attach to the N atoms at position 5 or 10, or are suspended between both N atoms (From Herbert and Zalusky,<sup>71</sup> courtesy of the authors and Journal of Clinical Investigation)

Folate is also required for steps in de novo purine synthesis, namely, transfer of carbons 2 and 8 to the purine ring.

Of clinical interest is another reaction involving folic acid: the reaction of the degradation product of histidine metabolism, formiminoglutamic acid (FIGlu) with  $\text{FH}_4$  to form glutamate and  $\text{N}^5$ -formimino- $\text{FH}_4$  (Fig. 4-3). In severe folic acid deficiency this reaction cannot occur and FIGlu, together with its immediate precursor, urocanic acid, appears in the urine unchanged. In deficient subjects, excretion can be greatly increased by the administration of histidine prior to the collection of urine. This has been used as a test for folic acid deficiency, as has the excretion of aminoimidazol-carboxamide (AIC) (Chapter 14). AIC, in the form of ribonucleotide, is formylated in vivo to yield formaminoimidazole carboxamide, an intermediate in de novo purine biosynthesis. In folate deficiency this conversion does not occur because the formyl group is contributed by  $\text{N}^{10}$ -formyl tetrahydrofolate.

#### Vitamin $\text{B}_6$ <sup>114</sup>

Vitamin  $\text{B}_6$  is a class name for several naturally occurring derivatives of 2-methyl-3-hydroxy-5-hydroxymethyl pyridine. The

major forms of the vitamin are pyridoxine, pyridoxal, pyridoxamine, and the phosphorylated derivatives of these three compounds (Fig. 4-4).

Vitamin  $\text{B}_6$  is widely distributed in foods of both plant and animal origin. Meat and grains are excellent sources, but relatively low concentrations are found in milk. The minimum daily requirement is approximately 1.5 mg<sup>27</sup> and the Food and Nutrition Board of the U.S. National Research Council recommends an intake of 1.5 to 2 mg per day in adults and 0.4 mg per day in infants.<sup>66</sup>

In a variety of animal species, experimentally induced deficiency of vitamin  $\text{B}_6$  leads to hypochromic, microcytic anemia, iron overload, and neurologic abnormalities.<sup>67,71,109,128,147</sup> The syndrome has been described in greatest detail in swine.<sup>44,183</sup> If the diet is complete in other respects, administration of pyridoxine brings about complete relief of the anemia.<sup>46</sup> Naturally occurring dietary deficiency in man is rare, apparently because of the ubiquitous distribution of the vitamin. With an artificial, pyridoxine-deficient diet, deficiency was induced in two hydrocephalic infants, one of whom developed hypochromic, microcytic anemia.<sup>160</sup> In the 1950's, an "epidemic" of seizures in infants was ascribed to deficiency of vitamin

Fig. 4-4. Chemical structure of various forms of vitamin  $\text{B}_6$ .

B<sub>6</sub> in a commercial infant-feeding formula.<sup>135</sup> Experimental deficiency has been induced in adults with the antivitamin, denxypyridoxine.<sup>131</sup> Evidence of naturally occurring, mild deficiency has been observed in malabsorptive states.<sup>111</sup> Also, there is biochemical evidence for mild vitamin B<sub>6</sub> deficiency in women taking contraceptive pills<sup>152</sup> and in those who are pregnant.<sup>37</sup> In pregnancy, there is probably no consequent increase in morbidity and mortality of either mother or fetus<sup>94</sup>; in particular, the claim that hyperemesis gravidarum responds to pyridoxine therapy was not supported by a controlled evaluation.<sup>92</sup> In a number of other clinical settings (eg, malignancy, hyperthyroidism, rheumatoid arthritis, epilepsy, and others),<sup>114</sup> vitamin B<sub>6</sub> deficiency was suggested by abnormalities in tryptophan metabolism. However, a more likely explanation for these abnormalities is an induced alteration in the activity of the hepatic enzyme, tryptophan pyrrolase.<sup>23</sup>

Certain drugs, including isoniazid (INH)<sup>33,124,144</sup> and penicillamine,<sup>104</sup> inactivate or inhibit vitamin B<sub>6</sub> and may lead to symptoms of deficiency. Also, several genetic syndromes that respond to pharmacologic doses of pyridoxine, even though there is no deficiency of the vitamin, have been described.<sup>114,130,155</sup> These syndromes include pyridoxine-responsive sideroblastic anemia (page 680), "pyridoxine-dependency" seizures in infants, cystathioninuria, homocystinuria, and xanthurenic aciduria.

Vitamin B<sub>6</sub> is absorbed rapidly and completely from the normal intestinal tract. Its active coenzyme forms are pyridoxal-5-phosphate (Fig. 4-4) and pyridoxamine-5-phosphate. These may be formed *in vivo* by two enzymatic reactions: the pyridoxal phosphokinase reaction, which accomplishes phosphorylation of all three members of the B<sub>6</sub> group,<sup>123</sup> and the pyridoxine phosphate oxidase reaction, which converts either pyridoxine phosphate or pyridoxamine phosphate to pyridoxal phosphate.<sup>172</sup> These reactions have been demonstrated to occur in erythrocytes.<sup>25</sup> The principal excretory product of vitamin B<sub>6</sub> is 4-pyridoxic acid, which is

formed from pyridoxal by a nonspecific aldehyde oxidase in the liver.

The vitamin B<sub>6</sub> coenzymes participate in a wide variety of reactions almost all of which are involved with amino acid metabolism. The reactions fall into three main categories: (1) decarboxylation, (2) transamination, and (3) molecular interchanges at the bond between the amino acid  $\alpha$ - and  $\beta$ -carbons. The requirement for vitamin B<sub>6</sub> in erythropoiesis appears to be chiefly related to this vitamin's role as a cofactor in the formation of aminolevulinic acid, the rate-limiting step in heme biosynthesis (page 169).

### Riboflavin

Deficiency of riboflavin (vitamin B<sub>2</sub>) leads to anemia in a variety of species, including rats,<sup>110,129</sup> baboons,<sup>69</sup> monkeys,<sup>173</sup> and pigs<sup>184</sup> (Table 4-2). In man, anemia has been induced by riboflavin deprivation and the administration of the riboflavin antagonist, galactoflavin.<sup>112</sup>

The anemia in these experimental situations is normocytic and normochromic and is associated with erythroid hypoplasia of the bone marrow and a reduced reticulocyte count. Vacuolization of the normoblasts is observed when deficiency is severe.<sup>69,112</sup> Plasma iron transport and erythrocyte iron incorporation are reduced. Thus, the hematologic picture includes the expected morphologic and kinetic features of decreased red cell production due to erythroid hypoplasia. Leukocytes and platelets usually are unaffected. When riboflavin is administered, reticulocytosis and return of the blood hemoglobin concentration to normal ensue.

Naturally occurring riboflavin deficiency in man is almost always associated with deficiencies of other nutrients. In such situations the clinical findings usually ascribed to lack of riboflavin are angular stomatitis and seborrheic dermatitis.<sup>101</sup> Nevertheless, anemia and erythroid hypoplasia, responding to riboflavin and not to other nutrients, have been reported occasionally.<sup>68</sup>

The precise role of riboflavin in red cell production has not been defined. However,

**Table 4-2. Hematologic Characteristics of Experimental Nutritional Deficiencies in Swine**

Deficiency	Anemia		Leukopenia	Plasma Iron	Serum Copper	E P	Bone Marrow Morphology
	Type	Severity					
Protein	N	+	None	Normal	Low	Normal	Normoblastic
Lysine	N	+	None	Normal	Normal	—	Normoblastic

Vitamin E <sup>132</sup>	N	++++	None	Normal	—	—	Abnormal*

Types of anemia: N indicates normocytic; MH microcytic hypochromic; Mi microcytic and Ma macrocytic.

E P refers to free erythrocyte protoporphyrin.

\*Hyperplasia with multinucleated cells.

the flavin coenzymes, flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), are involved in many aspects of intermediary metabolism,<sup>150</sup> especially in oxidation-reduction reactions. Among the important enzymes requiring flavin cofactors are xanthine oxidase, succinate dehydrogenase, NADPH cytochrome c reductase, and glycolic acid oxidase. Two flavin enzymes of special importance to the red cell are glutathione reductase (page 104) and NADH methemoglobin reductase (page 105), enzymes that are required for optimal survival and function of the erythrocyte. However, any relation to erythropoiesis has not been established.

### Pantothenic Acid

In spite of its importance in the biosynthesis of hemoglobin (page 171), deficiency of pantothenic acid, experimentally induced in swine, was associated with the development of only a moderate normocytic anemia.<sup>182</sup> In these swine, severe sensory neuron degeneration was induced as well as extensive colitis. In rats, lymphocytopenia was reported.<sup>35</sup> In man, experimentally induced pantothenic

acid deficiency was found to be associated with fatigue, headache, weakness, emotional lability, impaired motor coordination, paresthesias, muscle cramps, gastrointestinal disturbances, and eosinopenia, but anemia did not develop.<sup>80</sup>

### Nicotinic Acid (Niacin)

The significance of nicotinic acid in hemopoiesis has been obscure even though a role for this vitamin has been suspected since the importance of nicotinic acid in pellagra and in acute black-tongue in dogs was first demonstrated. In the latter condition the hemoglobin may not be reduced but even may be increased when the manifestations of the disorder are at their peak. It was shown, however, that the acute symptoms could be alleviated by the parenteral administration of normal saline solution. When the saline solution was given a profound anemia made its appearance.<sup>81</sup> The anemia was found to be macrocytic, hypochromic and normocytic, normochromic in type when two different nicotinic acid-deficient diets were fed. The anemia, which was severe, was not associated with evidence of exaggerated blood destruc-

tion. Following the administration of nicotinic acid there was an immediate reticulocyte response followed by restoration of normal production of red cells. In swine maintained on a low-protein, niacin-deficient diet, normocytic anemia that responded to either protein or niacin therapy developed.<sup>39</sup> Since nicotinic acid is concerned in the synthesis of pyridine nucleotides (NAD, NADP) and thus in cell respiration, a lack of this vitamin may interfere with the respiration of immature red cells.

### Other B Vitamins

Although, by their participation in various metabolic processes, other B vitamins, such as biotin<sup>110,153</sup> and thiamin,<sup>118,186</sup> must play some role in hematopoiesis, no well-defined alterations in the blood picture have been observed in association with deficiencies of these nutrients.

### Ascorbic Acid

Ascorbic acid (vitamin C) deficiency does not occur in all species. It occurs in man, as in the monkey<sup>29</sup> and the guinea pig, because he does not possess the enzyme system required for the production of L-ascorbic acid from glucose.<sup>39</sup> Scurvy, the clinical syndrome attributed to vitamin C deficiency, frequently is associated with deficiencies of other essential nutrients. It is not surprising, therefore, that the anemia usually present in scurvy has been reported as being normocytic, macrocytic, or hypochromic, microcytic.<sup>53,74</sup> The bone marrow is usually quite cellular, with a relative increase of normoblasts,<sup>170</sup> but occasional megaloblasts have been reported.<sup>36</sup> Leukopenia is found sometimes; thrombocytopenia, rarely. Persistent reticulocytosis, indirect bilirubinemia, increased urinary urobilinogen, decreased plasma haptoglobin, and methemalbuminemia have been observed in some subjects.<sup>53,74,170</sup> It has been claimed that these changes are not solely attributable to absorption of pigment from extravascular hemolysis in the hematomas; the survival time of labeled erythrocytes from a normal com-

patible donor transfused to patients with scurvy was found to be shortened,<sup>74,126</sup> thus suggesting the presence of a hemolytic process. However, this is not found in all cases.<sup>43</sup>

Deliberately induced ascorbic acid deficiency lasting up to 39 months has not been associated with the development of anemia, even when blood loss by venesection totaled 6000 ml.<sup>54</sup> In another well-controlled study of human vitamin C deficiency, hemoglobin regeneration took place spontaneously or in response to iron therapy without the addition of ascorbic acid.<sup>117</sup>

In monkeys fed milk diets deficient in ascorbic acid, megaloblastic anemia was produced.<sup>122</sup> The experimental megaloblastosis could be eliminated or prevented by giving folic acid or folic acid without the addition of ascorbic acid and could be cured by giving ascorbic acid alone. Vitamin B<sub>12</sub> had no influence on the deficiency. If supplementary folic acid was given, when scurvy appeared the anemia was normoblastic rather than megaloblastic. As scurvy progressed, hemorrhage occurred and iron deficiency ensued. These experiments were interpreted as indicating that ascorbic acid serves no specific function in hematopoiesis, but that the requirements for folic acid and for iron are increased in scurvy. More probably, ascorbic acid exerts its effect by protecting folate in the diet from damage during heat and storage, rather than by affecting folate metabolism. In scurvy in man, low serum folic acid activity is not unusual<sup>18,53</sup> and associated folic acid deficiency no doubt often is present.

There is evidence that ascorbic acid may be required for normal iron metabolism.<sup>33,115</sup> In the Bantu with severe iron overload, the plasma iron level usually is markedly increased, but if the condition is complicated by scurvy, the plasma iron is low.<sup>33</sup> Administration of ascorbate to such patients leads to a prompt rise in plasma iron. In scorbutic guinea pigs, evidence of diminished release of iron from reticuloendothelial cells was presented.<sup>115</sup> As a result of the defect, storage iron increased in the spleen. Still other abnormalities were found in iron storage; thus, in contrast to the spleen, hepatic iron was

reduced, and in both organs the ferritin:hemosiderin ratio was decreased. The abnormalities could be corrected by administering ascorbate.

### Vitamin E and Other Fat-Soluble Vitamins

There is no evidence for any specific need for vitamin A, D, or K in erythropoiesis; however, a growing body of information indicates a requirement for vitamin E. Vitamin E was recognized as an essential nutrient as a result of the studies of Evans and Bishop.<sup>60</sup> In 1936,  $\alpha$ -tocopherol was isolated from wheat-germ oil and shown to have the biologic properties of vitamin E.<sup>61</sup> Structurally,  $\alpha$ -tocopherol consists of a heterocyclic chroman ring with a 16-carbon, aliphatic side chain (Fig. 4-5). Seven other naturally occurring forms of vitamin E have been discovered, all with considerably less activity than  $\alpha$ -tocopherol.<sup>175</sup>

Experimentally induced vitamin E deficiency in several animal species resulted in muscular dystrophy, reproductive failure, myocardial degeneration, renal tubular failure, and hepatic necrosis.<sup>134-175</sup> Hematologic manifestations were of two different types: a hemolytic anemia of varying severity and a profound disturbance of erythropoiesis. The latter was described most completely in monkeys,<sup>65,82,142</sup> but also was observed in swine.<sup>133</sup>

In monkeys, a long period of vitamin E deprivation (up to two years) was required before anemia occurred. The erythrocytes usually were found to be normocytic and normochromic, but sometimes were slightly

macrocytic. Erythrocyte survival was mildly to moderately reduced, but reticulocyte numbers were normal or only slightly increased. Erythrocytes were abnormally sensitive to hemolysis *in vitro* when exposed to hydrogen peroxide or dialuric acid. The serum iron concentration was normal. The bone marrow was hyperplastic, and the erythrocyte precursors were morphologically abnormal in that many were bi- or multinucleated. These changes were similar to those seen in congenital dyserythropoietic anemias (Chapter 19). In addition, the nuclear chromatin of erythroblasts appeared more homogeneous and more deeply stained than normal; however, the cells did not resemble megaloblasts.

After the administration of a single dose of 100 mg  $\alpha$ -tocopherol, reticulocytosis ensued and the blood hemoglobin concentration returned to normal. One form of coenzyme Q, hexahydrocoenzyme Q<sub>10</sub>, also could induce hematologic remission in vitamin E-deficient monkeys<sup>62</sup>; however, coenzyme Q<sub>10</sub>, the naturally occurring form of this coenzyme, induced reticulocytosis but little or no improvement in the anemia.<sup>65</sup>

Usually, only the hemolytic aspects of experimentally induced vitamin E deficiency have been detected in rats and mice.<sup>65</sup> Anemia was not found under ordinary circumstances, but the erythrocytes were sensitive to peroxide hemolysis *in vitro*. Furthermore, when the animals were exposed to hyperbaric oxygen, a severe hemolytic episode ensued. Administration of parenteral iron also induced hemolysis in these animals.<sup>139</sup>

Vitamin E deficiency is rare in man. The vitamin is distributed in a wide variety of foods, especially foods rich in fats and oils,

Fig 4-5. Chemical structure of  $\alpha$ -tocopherol, the principal form of vitamin E (From Silber and Goldstein,<sup>136</sup> courtesy of the authors and Grune & Stratton)

but also in grains.<sup>156</sup> The adult requirement, which may be as little as 5 mg per day or as much as 30 mg per day, probably is obtained from the great majority of diets. The need for vitamin E is related to the unsaturated fat content of the diet, and the fact that diets low in vitamin E tend also to be low in unsaturated fat is another reason for the rarity of nutritional vitamin E deficiency in man.<sup>116</sup>

In *premature infants*, vitamin E deficiency was found to be associated with low serum vitamin E levels, hemolytic anemia, and sensitivity of the erythrocyte to peroxide hemolysis, all of which could be corrected by administration of  $\alpha$ -tocopherol.<sup>77,139,149</sup> The hemolysis appeared to be aggravated by administration of iron and by the high oxygen atmospheres to which premature infants are frequently exposed.<sup>77</sup> Thus, the syndrome resembled that seen in small rodents, but had none of the dyserythropoietic features observed in monkeys and swine.

Vitamin E deficiency also has been suspected in occasional patients with *malabsorption*. They have been found to develop low serum tocopherol levels, reduced red cell survival, and increased sensitivity of erythrocyte to peroxide hemolysis.<sup>32</sup> The importance of vitamin E deficiency in the pathogenesis of the anemia of *kwashiorkor* (page 136) is disputed. Some observers have reported dramatic hematologic responses to vitamin E in patients with this disorder<sup>119</sup>; however, the detection of marrow megaloblastosis and reduced serum folate levels in these patients raises the possibility that they responded instead to folate in the hospital diet.<sup>156</sup> Furthermore, other investigators have found no response to vitamin E in *kwashiorkor* subjects.<sup>28</sup>

The role of vitamin E in biologic processes in general, or in hematopoiesis in particular, remains controversial. The best established biochemical property of this vitamin is that of an antioxidant. It has therefore been suggested<sup>167,185</sup> that, by combining with free radicals, vitamin E serves to prevent the chain of reactions called "lipid peroxidation" or rancidification.<sup>57,125</sup> By this mechanism,

oxidative damage to lipid membranes, including the red cell membrane and the membranes of mitochondria and other organelles, might be prevented. This hypothesis provides a good explanation for the hemolytic aspects of the anemia in vitamin E deficiency and for the observed sensitivity of the erythrocytes to peroxide, hyperbaric oxygen, dialuric acid, iron, and other substances capable of inducing or catalyzing lipid peroxidation. Such abnormalities might well arise from oxidative damage to the red cell membrane. The erythropoietic defects are less well explained by oxidative damage, unless they can somehow be related to impaired function of membranous organelles.

An alternative hypothesis holds that vitamin E has another, more specific metabolic function.<sup>76,154</sup> Advocates of this viewpoint maintain that efforts to establish the occurrence of lipid peroxidation *in vivo* have been generally unsuccessful. Furthermore, the antioxidant activity can be dissociated from the vitamin properties in certain compounds; eg,  $\delta$ -tocopherol is a better antioxidant *in vitro* than  $\alpha$ -tocopherol, but has much less biologic vitamin E activity.<sup>154</sup> The nature of this hypothetical function for vitamin E remains obscure. There is evidence that the vitamin may be a structural component of biologic membranes,<sup>118</sup> that it is essential to mitochondrial oxygen utilization,<sup>154</sup> and that it affects induction and repression of certain enzyme systems.<sup>134</sup> Pertinent to the role in erythropoiesis are observations suggesting a requirement for vitamin E in heme biosynthesis.<sup>41,132,134</sup> However, the hematologic findings in *anemic, vitamin E-deficient animals* are not of the kind usually found in association with disorders of heme synthesis.<sup>65</sup>

### Minerals

As a constituent of hemoglobin, iron is essential for erythropoiesis. Iron metabolism will be discussed later in this chapter (page 154). Roles in erythropoiesis have been attributed to many other minerals, but of these only copper and cobalt deserve serious consideration. It is noteworthy that commercial

iron preparations contain, as contaminants, small amounts of copper, manganese,<sup>250</sup> and even cobalt.<sup>255</sup> Anemia has been observed in offspring of magnesium-deprived, pregnant rats, but not in magnesium-deficient, adult animals.<sup>210</sup> There is no adequate evidence that manganese,<sup>212</sup> germanium, molybdenum, nickel, vanadium, or zinc has erythropoietic activity.<sup>248</sup> Calcium and phosphorus influence erythropoiesis only insofar as they affect iron assimilation (page 156).

## Copper

Anemia has been observed in experimental copper-deprivation in rats,<sup>218,250</sup> chickens,<sup>227</sup> and dogs<sup>203,231</sup>; the most extensive studies have been made in swine.<sup>231,232</sup> The anemia is characterized morphologically by hypochromia and microcytosis of the erythrocytes, changes that imply defective biosynthesis of hemoglobin. This defect appears to be a consequence of several abnormalities in iron metabolism, including impaired iron absorption, defective transfer of iron from reticuloendothelial cells and hepatocytes to plasma, and failure of the normoblast to utilize intracellular iron for hemoglobin synthesis.<sup>232</sup>

In addition to anemia, signs of copper deficiency include abnormalities in the synthesis of elastin, leading to dissecting aneurysms and intramural hemorrhages affecting major blood vessels.<sup>213</sup> Abnormalities of color and character of hair and wool have been observed as well as deformities of bones.<sup>256</sup> In second-generation copper deficiency in sheep, an extensive demyelinating neurologic disease known as "swayback" or enzootic neonatal ataxia occurs.<sup>256</sup>

## Copper Metabolism

Copper metabolism in man has been the subject of several reviews.<sup>201,209,217,216</sup> The total body copper content is about 80 mg. Copper is found in all tissues, and is probably a functional constituent of all living cells.<sup>235</sup> The highest concentrations are found in the liver, brain, and heart.

Copper is absorbed from the small in-

testine and upon entering the circulation becomes bound to albumin. This so-called "direct-reacting" fraction of plasma copper, though small in relation to ceruloplasmin copper, occupies a pivotal position in copper metabolism (Fig. 4-6). From this pool, copper is distributed to the liver, bone marrow, and other tissues. The plasma pool also receives copper from the tissues and from it is derived the copper that is excreted through the urinary tract (4%) and the intestinal wall (16%). The largest proportion (80%) of body copper loss occurs through the bile. Thus, the direct-reacting fraction reflects the turnover of copper between the gastrointestinal tract, the tissues, and the excretory routes.

The principal copper protein in plasma is ceruloplasmin, a blue glycoprotein with the electrophoretic mobility of an  $\alpha_2$ -globulin.<sup>205,225</sup> It has a molecular weight of 160,000 and seven molecules of copper (0.32%) are incorporated within its structure. Ceruloplasmin copper must be liberated from the protein before it can be measured and is therefore termed "indirect-reacting." Ceruloplasmin possesses oxidase activity toward a variety of substrates,<sup>238,259</sup> one of which is ferrous iron.<sup>239</sup> The ferrous-oxidizing (ferroxidase) activity of ceruloplasmin appears to be essential to normal iron mobilization, as will be discussed below.

The total serum copper (mean and 95% limits) is 114 (81 to 147)  $\mu\text{g/dl}$  or 13 to 23  $\mu\text{mol/l}$ . Slightly higher values are found in women (120  $\mu\text{g/dl}$ ) than in men (109  $\mu\text{g/dl}$ ). Of the total, 7 (0 to 20)  $\mu\text{g/dl}$  are "direct-reacting" (albumin-bound), and the remainder is "indirect-reacting." The normal ceruloplasmin is 31 (25 to 37)  $\text{mg/dl}$  in men, and 36 (25 to 47)  $\text{mg/dl}$  in women.

Variations in serum copper occur in different clinical conditions.<sup>230</sup> Hypercupremia is found frequently. It occurs in normal pregnancy, especially in the last trimester, in various subacute and chronic infections, and in a variety of diseases, including Hodgkin's disease, acute leukemia, aplastic anemia, hyperthyroidism, and hemochromatosis. Less consistently, it is found in chronic leukemia, lymphosarcoma, pernicious and iron-

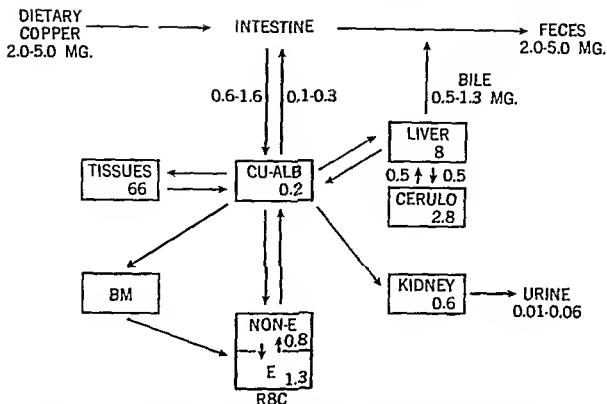

Fig 4-6. Schematic representation of some metabolic pathways of copper. The numbers in the boxes refer to milligrams of copper in each pool. The numbers next to the arrows refer to milligrams of copper traversing the pathway each day. CU-ALB direct reacting fraction, CERULO ceruloplasmin, NON-E non-erythrocyte fraction of red corpuscles (RBC), E, erythrocyte, BM, bone marrow. (Prepared by Dr. G. E. Cartwright.)

deficiency anemias (especially in infants), and in collagen disorders. These changes usually result from an increase in plasma ceruloplasmin, which, along with fibrinogen and certain other plasma proteins, is considered to be an "acute phase reactant" (see sedimentation rate, page 127).

Hypocupremia,<sup>209</sup> on the other hand, is uncommon. It tends to be found when syn-

thesis of serum proteins is low, when absorption is impaired, or when protein is being lost in large quantity (Table 4-3). It is characteristic of Wilson's disease. The level of ceruloplasmin in the serum of the newborn is about half that in the serum of adults.

Total erythrocyte copper ranges from 66 to 112  $\mu\text{g}/\text{dl}$  packed red cells. Of this, 60% is accounted for by a faintly greenish-blue protein called erythrocyte copper.<sup>253</sup> Similar or identical proteins are found in other tissues, especially the liver and brain, and the general term "cytochrome" has been proposed to apply to all such proteins.<sup>208</sup> Highly purified human erythrocyte copper has been prepared and partially characterized.<sup>256</sup> It has a molecular weight near 33,600 and contains 2 g atoms (0.38%) copper. Erythrocyte copper has been shown to have superoxide dismutase activity; i.e., it catalyzes the conversion of the superoxide anion radical ( $\text{O}_2^{\cdot-}$ ) to molecular oxygen and peroxide.<sup>256</sup> The biologic significance of this reaction is uncertain, but it may

protect cellular elements from the damaging effects of superoxide.

Copper is known to be a constituent of a number of other enzymes, most of which are oxidases.<sup>221</sup> Examples are cytochrome oxidase, laccase,<sup>206</sup> ascorbic acid oxidase,<sup>238</sup> tyrosinase, and monoamine oxidase.<sup>263</sup>

### *Deficiency in Man*

Since copper is widely distributed in food-stuffs and is commonly present as a contaminant in water, diets of even mediocre quality contain amounts of copper that are adequate for the normal human adult.<sup>246</sup> The average diet furnishes 2 to 5 mg copper daily, and copper balance can be maintained on less than 2 mg per day.<sup>209</sup> However, cow's milk contains relatively little copper; consequently, it would seem possible for infants to become deficient under certain circumstances. Indeed, a syndrome characterized by anemia, edema, hypoproteinemia, hypoferrinemia, protein-losing enteropathy, and hypocupremia was reported in a number of infants.<sup>209</sup> However, treatment with iron alone corrected all of the observed abnormalities except the hypocupremia, whereas treatment with copper alone corrected the hypocupremia without relieving the anemia. These observations indicate that the syndrome cannot be ascribed to copper deficiency alone; indeed, iron deficiency seems to account for all of the findings except the reduced levels of copper in the serum.

In addition to the hypocupremia reported in infants, occasional cases of copper depletion to a degree sufficient to cause hypocupremia have been reported in persons with kwashiorkor, and in some with tropical and nontropical sprue, or with the nephrotic syndrome.<sup>209</sup> Furthermore, severe anemia, neutropenia, bone changes, and hypocupremia were reported in four severely malnourished infants. These infants were rehabilitated on diets high in calories but low in copper.<sup>211</sup> In two of them the response to copper was dramatic, whereas in the other two the effect of copper was less definite.

### *Role in Erythropoiesis*

The abnormalities in iron metabolism leading to the anemia of copper deficiency are only partially understood. Ceruloplasmin appears to be required for optimal flow of iron from cells to plasma. When severe hypoceruloplasminemia is induced experimentally, reticuloendothelial cells fail to release their iron at a normal rate, and this leads to hypoferrinemia in the presence of normal iron stores.<sup>232,244</sup> The abnormality can be promptly corrected by injecting ceruloplasmin intravenously.<sup>243,244</sup> Ceruloplasmin is presumed to act by catalyzing the oxidation of ferrous iron to the ferric form, which is a prerequisite for iron binding by apotransferrin.

The anemia of copper deficiency is not completely explained by defective ceruloplasmin function, however. There is evidence for two other defects. One of these affects intracellular iron metabolism in the normoblast<sup>232</sup>; as a result, iron cannot be used for hemoglobin synthesis and, instead, accumulates within the cytoplasm, forming sideroblasts. This abnormality probably relates to defective mitochondrial iron uptake.<sup>261</sup> The other erythrocyte abnormality, probably a membrane defect,<sup>233</sup> leads to shortened erythrocyte survival.<sup>207</sup> These observations imply that copper proteins are required for intracellular iron utilization and for optimal erythrocyte membrane function; however, the nature and mechanism of action of copper in these steps have not been elucidated.

### *Cobalt*

Cobalt is an essential trace element in the sense that it is a component of the vitamin B<sub>12</sub> molecule (page 137). Only microorganisms are able to utilize cobalt to form vitamin B<sub>12</sub>, and the microorganisms that inhabit the rumen of multigastric animals play a particularly important role in production of the vitamin. In geographic areas in which cobalt-deficient soils are found, such as the British Isles, Australia, New Zealand, and Florida, a malady of ruminants due to

cobalt deficiency has been observed and is variously termed "pining coast disease," "enzootic marasmus," "bush disease," and "salt sickness."<sup>235</sup> The condition is characterized by unthriftiness, progressive wasting, and profound macrocytic<sup>235</sup> or normocytic<sup>234</sup> anemia as well as hemosiderosis.<sup>255</sup> It is not accompanied by neurologic changes. The disorder can be relieved when cobalt is administered orally, but not when it is given intravenously. The significance of these findings was clarified by the discovery that cobalt is incorporated into vitamin B<sub>12</sub> in the rumen.

The experimental production of cobalt deficiency<sup>222</sup> is made difficult by the low requirement for cobalt. Cobalt deficiency does not seem to occur naturally except in ruminants. It is noteworthy that nonruminant, herbivorous animals remained healthy when confined to pastures on which cattle and sheep developed enzootic marasmus.<sup>235</sup> Interestingly, the livers of ruminants are a more potent source of vitamin B<sub>12</sub> than are those of pigs or rats.<sup>232</sup>

Cobalt is ubiquitous. It is found in small concentrations in foods, water, beverages, and in mammalian tissues and body fluids.<sup>247</sup> Concentrations in tissue are greatest in the liver, heart, and adipose tissue. The dietary intake of cobalt ranges from 140 to 580 µg/day and urinary excretion equals about 85% of the intake. During absorption, cobalt apparently follows pathways also utilized by iron<sup>215,257</sup> (see Chapter 16, page 630), and many of the factors that enhance iron absorption have the same effect on cobalt. Because of its ubiquitous distribution in food, the fact that it is readily absorbed and excreted and does not accumulate with age, and its ability to act as a catalyst and form chelates,<sup>247</sup> cobalt has been suspected as being an essential trace metal in ways other than as a constituent of vitamin B<sub>12</sub>. Nevertheless, no other requirement for nor function of cobalt has been discovered.

### *Cobalt Polycythemia*

The administration of cobalt in quantities far in excess of the normal dietary require-

ment results in the production of polycythemia in many species of animals.<sup>248</sup> This is due to a true increase in red cell mass<sup>237</sup> and is accompanied by reticulocytosis, hyperplasia of the bone marrow, and increased erythropoietic activity in the liver and spleen.<sup>218</sup> It is thought that cobalt acts by inhibiting enzymatic activities that deal with the transport of oxygen and that the resulting tissue anoxia produces polycythemia. The cobaltous ion is known to have a marked inhibitory action *in vitro* on the endogenous respiration of a number of tissues. By attaching irreversibly to the reduced disulfide groups of the cofactor, lipoic acid, cobalt blocks the conversion of pyruvate to acetyl coenzyme A and of  $\alpha$ -ketoglutarate to succinate—two steps of vital importance to cellular respiration.<sup>260</sup> The influence of cobalt in producing polycythemia can be lessened maternally by the inclusion in the diet of sufficient sulfur-containing amino acids.<sup>224</sup> These substances, especially cysteine,<sup>237</sup> are known to chelate with cobalt.

Other studies suggest that cobalt stimulates the formation of erythropoietin (page 180). This seems to be the mechanism whereby cobalt overcomes the anemia induced in animals by hypophysectomy<sup>214</sup> and possibly that of protein deficiency.<sup>237</sup> However, direct stimulation of erythropoiesis in the isolated hind limb by cobalt also has been reported.<sup>219</sup>

The administration of cobalt in large amounts simultaneously with the experimental induction of inflammation was found to prevent the development of anemia resulting from the inflammation.<sup>262</sup> Likewise, in patients with various types of anemia refractory to other forms of antianemic therapy, such as anemia associated with infection,<sup>264</sup> renal disease,<sup>223</sup> or cancer,<sup>251</sup> the daily oral administration of 20 to 300 mg, but more usually 60 to 150 mg, of cobaltous chloride is associated with reticulocyte increases and some relief of the anemia. Claims that hemoglobin regeneration in patients with iron-deficiency anemia is more rapid when cobalt-iron mixtures are given than the regeneration resulting from iron therapy alone are not convincing. Also, reports that cobalt im-

proves iron utilization in the anemia of prematurity<sup>214, 212</sup> fail to offer any observations on the effect of iron therapy as compared with iron-cobalt therapy in parallel series of infants. Cobalt therapy relieved the anemia in a patient with "acquired erythrocytic hypoplasia,"<sup>249</sup> but a significant effect in patients with hypoplastic or aplastic anemia seems to be the exception<sup>204</sup> rather than the rule.

The prolonged administration of cobaltous chloride in the doses cited may be associated with anorexia, nausea, and vomiting. More serious is the possibility of cardiac toxicity. A fulminating cardiomyopathy occurred in a number of individuals following consumption of beer to which cobalt had been added as an antifoaming agent.<sup>202</sup> Less frequent ill effects include flushing of the face and extremities, skin rash, tinnitus and nerve deafness, substernal pain, and even thyroid hyperplasia associated with thyroid hypofunction.<sup>229</sup>

Not only is cobalt potentially toxic, but also patients with anemia associated with infection or cancer who were treated with cobalt seemed to derive no real benefit even though the anemia became less severe. In patients with renal anemia,<sup>223</sup> cobalt therapy was associated with improved appetite and greater tolerance for medications necessary to correct electrolyte abnormalities. However, the increased blood values promptly declined to pretreatment levels when cobalt therapy was discontinued. It appears, therefore, that the uses of cobalt as a therapeutic agent are very limited.

## Zinc

Zinc<sup>210</sup> is found in red corpuscles, leukocytes, and plasma. The zinc in red corpuscles is mainly attributable to the content of carbonic anhydrase in these cells,<sup>258</sup> but a portion of the zinc in erythrocytes exchanges freely with the body pool of zinc.<sup>215</sup> The zinc content of erythrocytes is increased in megaloblastic anemia, in chronic leukemias, acute lymphoblastic and monocytic leukemia, and in myeloid metaplasia.<sup>220</sup> A reciprocal rela-

tionship between the levels of zinc in erythrocytes and leukocytes in various diseases has been noted. Low values in leukocytes were found in patients with conditions in which erythrocyte values were high. It is assumed that the zinc metalloprotein of leukocytes is an enzyme or group of enzymes, but no correlation with a number of specific enzymes could be established.<sup>258</sup>

Although zinc deficiency was thought to be the cause of growth retardation, hypogonadism, and partial adrenal hypofunction in clay-eating patients in Iran and in Egypt, it was not found to be related to the iron-deficiency anemia also encountered in many of these subjects.<sup>241</sup> "Meat anemia," described in mice, was found to be due to dietary lack of copper associated with an excess of zinc.<sup>225</sup>

## Iron Metabolism

### Total Body Iron

The body iron content of a normal, adult male is approximately 50 mg/kg body weight, whereas that of adult women is about 35 mg/kg.<sup>316</sup> This male-female difference reflects the high incidence of iron deficiency in women and should not be taken to mean that there are fundamental differences in iron metabolism between the sexes. Of the total body iron, only a minute portion (less than 0.1%) is found in the plasma, where it is carried in bond with a serum  $\beta_1$  globulin (transferrin). The remainder is either bound in a porphyrin ring as a part of hemoglobin, myoglobin, or one of the heme enzymes (Table 4-4), or is laid aside as storage iron. The storage forms of iron, ferritin and hemosiderin, constitute normally about 30% of the body iron, or about 1 g in men. Smaller stores, 200 to 400 mg, are found in women.<sup>316</sup>

### Iron Balance

The total iron content of the body tends to remain fixed within relatively narrow limits, otherwise siderosis or iron deficiency oc-

Table 4-4. Approximate Composition of the Iron-Containing Compounds in the Human (70-kg Man)<sup>344</sup>

Compound	Total Amount (g)	Iron Content (g)	% of Total Fe
<i>Iron porphyrin (heme) compounds</i>			
Blood hemoglobin . .	800	2.67	66.7

Total iron . .	—	4.0	100

curs. It follows that losses of iron must be matched by the absorption of iron from food. Iron is not "excreted" in the usual sense of the word. It is lost from the body only when cells are lost, especially epithelial cells from the gastrointestinal tract. Urinary iron amounts to less than 0.05 mg/day, and is largely accounted for by desquamated cells. In women, menstrual flow constitutes an important additional route of iron loss. On the basis of long-term studies of body iron turnover, the average daily loss of iron has been estimated at about 1.0 mg (range 0.6 to 1.6 mg) in normal, adult men and non-menstruating women.<sup>345</sup> About twice this amount is lost in menstruating women.<sup>350,362</sup> In pregnant women, the rate of iron loss is about 3½ times as great as in normal men (Table 17-6, page 648).

In the normal situation, these losses are balanced by an equivalent amount of iron absorbed from the diet. The average intake of iron in the American diet is about 6 mg per 1000 calories<sup>316</sup> or between 10 and 30 mg per day, but there is much greater variation than this in different parts of the world and under various circumstances.<sup>374</sup> Assuming that 1 mg enters the body to balance the amount lost, only 5 to 10% of dietary iron is absorbed. This proportion can increase some three- to fivefold if iron stores are

depleted. Conversely, the proportion absorbed decreases in states of iron overload.<sup>407</sup> Thus, iron balance is unique in that it is achieved by control of absorption rather than control of excretion. How this control is accomplished has been the subject of much controversy.

Iron is absorbed chiefly in portions of the intestine proximal to the mid-jejunum, and absorptive capacity is much less in more caudal intestinal segments.<sup>408</sup> This localization is partly related to such intraluminal factors as pH and redox potential. However, in experiments with isolated gut loops<sup>353</sup> and in *ex vivo*, inverted sac preparations,<sup>391</sup> as well as in studies of isolated mucosal cell brush borders,<sup>346</sup> a decreasing capacity to absorb iron as more caudal segments were studied could be demonstrated without relation to intraluminal factors.

In man and other omnivorous mammals, there appear to be at least two distinct pathways for iron absorption, one for iron attached to heme<sup>314,402,409</sup> and another for iron in the form of ferrous ion (or, possibly, soluble ferrous chelates).<sup>375</sup> Dietary iron must be converted to one of these two forms in order to be absorbed. Heme iron is derived from the hemoglobin, myoglobin, and other heme proteins in foods of animal origin. Exposure to the acid and proteases of gastric

juice frees the heme from its apoprotein, whereupon the iron is probably oxidized to the ferric state, forming hemin. This molecule enters the mucosal cell intact<sup>405</sup> and then is metabolized as will be discussed below. Other forms of food iron must be converted to the ferrous form to be absorbed.<sup>375</sup> Since the ease with which this conversion is accomplished differs according to the nature of the iron compounds, the "availability" of food iron is quite variable.<sup>374</sup> In foods derived from grains, iron often forms a stable complex with phytates and only small amounts of such iron can be converted to the absorbable form.<sup>393</sup> Similarly, the iron in egg yolk is not readily absorbed, probably because it is complexed with phosphates or phosphoproteins.<sup>374</sup> The exact nature of iron in many other foods is not known. However, it appears to be mainly in the ferric state, much of it as ferric hydroxide or loosely bound to organic molecules such as sugars, citrate, lactate, and amino acids.

Various *intraluminal factors* influence non-heme iron absorption,<sup>323</sup> but have no effect on heme iron. These factors act by affecting the ease with which the ingested forms of non-heme iron are converted to, or maintained in, the ferrous state. Thus, reducing agents, such as ascorbic acid and cysteine, facilitate absorption. The acid gastric juice is a medium in which solubilization and reduction of iron are favored; consequently, absorption of ferric iron is impaired in subjects with gastrectomy or achlorhydria,<sup>319,355,356,373,379</sup> as well as in rats with radiation-induced achylia gastrica.<sup>379</sup> However, intrinsic factor is not required for iron absorption.<sup>352</sup> Compounds forming soluble ferrous chelates, such as fructose and other keto sugars<sup>323</sup> and certain amino acids,<sup>404</sup> increase absorption. On the other hand, compounds forming insoluble complexes with iron, such as the aforementioned phytates and phosphates as well as oxalates, decrease absorption. Calcium in the diet may facilitate iron absorption by competing with iron in the formation of these complexes.<sup>303</sup>

Certain gastrointestinal secretions have been alleged to be among the intraluminal

factors influencing iron absorption. Initial reports indicated that pancreatic secretions contain a factor that decreases iron absorption.<sup>314</sup> It was proposed that the pancreas might play an important role in regulation of iron absorption and in the pathogenesis of hemochromatosis.<sup>326</sup> However, evidence for this hypothesis has been found wanting.<sup>323</sup> Similarly, a gastric iron-binding component called "gastroferrin" was found to be decreased in patients with iron deficiency and hemochromatosis,<sup>327</sup> but the physiologic importance of this substance, possibly a carbohydrate,<sup>378</sup> remains to be demonstrated.

Iron absorption takes place in two distinct steps: (1) mucosal uptake, and (2) transfer of iron from the mucosal cell to the lamina propria, where it enters plasma.<sup>358,391,407</sup> Both steps probably represent energy-dependent, active transport processes, although some have suggested that a non-energy-dependent, carrier-mediated mechanism exists.<sup>353</sup> Mucosal uptake occurs rapidly at the brush border of the mucosal cell.<sup>307,346</sup> Within the next few hours, the newly acquired iron is found to be associated with the rough endoplasmic reticulum and with free ribosomes.<sup>307</sup> Some of it may be present in cytoplasm as unbound iron salts or complexes of low molecular weight.<sup>394</sup> A variable proportion of iron taken into the cell is delivered to the plasma within a few hours.<sup>383</sup> The remainder probably is incorporated into mucosal ferritin,<sup>315,394</sup> an intracellular iron protein that will be discussed in a later section (page 162). Much of the mucosal ferritin iron appears to be sloughed into the intestine with the mucosal cell after the latter has completed its three- to four-day life span.<sup>324</sup> However, a "delayed phase" of iron absorption has been observed that occurs between 3 and 24 hours and may represent mobilization from ferritin or other intracellular binding sites.<sup>383</sup>

When heme iron enters the cell, the porphyrin ring is cleaved by an enzyme,<sup>405</sup> possibly xanthine oxidase,<sup>328</sup> and the liberated iron thereafter follows the same pathways as those utilized by ionic iron. A small proportion of the heme iron may pass into the

plasma intact<sup>405</sup> and become bound to the heme-binding protein, hemopexin.

Since the total body iron content depends so greatly on absorption of iron, the mechanisms by which the rate of absorption is regulated have been of great interest for many years. Two factors are of prime importance in determining absorptive rate. The first of these is the amount of storage iron—when it is depleted, iron absorption is increased; when it is excessive, iron absorption is decreased. The second factor is the overall rate of erythropoiesis, whether “effective” or “ineffective.” Iron absorption is increased when the red cell production rate is increased and absorption is decreased when production is decreased.

The manner in which these two factors influence the function of the mucosal cell remains the subject of active speculation and investigation. The “mucosal block theory” held that there are a limited number of iron acceptor sites within the intestinal mucosa; if these are saturated, either exogenously or endogenously, a block in further iron absorption results.<sup>348</sup> In an extension of the theory, apoferritin was postulated to be the iron acceptor and ferritin synthesis was thought to be an intermediate in the absorptive process.<sup>344</sup> This theory gradually lost favor, however, when it was demonstrated that iron is absorbed even when tissues are laden with deposited iron.<sup>331,334,397</sup>

A modified version of the mucosal block theory has been put forward on the basis of a series of experiments in rats<sup>317,324,407</sup> (Fig. 4-7). These studies showed that endogenous iron was incorporated into mucosal cells as they were formed in the crypts of Lieberkühn. It was proposed that the subsequent absorptive behavior of the mucosal cell is regulated by the amount of this “messenger iron,” more than normal being incorporated when iron stores are excessive or erythropoiesis is depressed, and reduced amounts being incorporated in iron-deficiency states or during accelerated phases of erythropoiesis. Depending on this “message,” iron taken up from the gut can either proceed into the plasma or be incorporated into ferritin to be

sloughed at the end of the life span of the mucosal cell. The failure to demonstrate significantly reduced amounts of non-heme iron in mucosal epithelial cells in iron-deficient rats with increased iron absorption has been cited as evidence against the hypothesis.<sup>306</sup> Others, however, found mucosal iron to be reduced in a supernatant fraction of mucosal homogenate from both iron-deficient and hemolyzing animals.<sup>394</sup> It is possible that the “messenger iron” enters a critical subcellular location such as the mitochondria,<sup>410</sup> or that it partially saturates a “carrier” essential to absorption.<sup>383,384,400</sup>

Efforts also have been made to demonstrate that the control of iron absorption is humoral in nature. No such humoral factor could be found in plasma from iron-deficient animals.<sup>309</sup> However, evidence of a possible inhibitor of iron absorption was found in the plasma of iron-loaded rats.<sup>368</sup>

### The Iron Cycle

The metabolism of iron is dominated by its role in hemoglobin synthesis. In this process, iron is utilized over and over again, so that, for the most part, the internal movements of iron may be described as a cycle (Fig. 4-8). Central to this cycle is the plasma iron compartment, in which iron is bound to a transport protein, transferrin. Iron moves from plasma to cells that have the capacity to make hemoglobin. When synthesis is complete, the iron, now in the form of hemoglobin in mature red corpuscles, is delivered to the circulation. At the end of their 120-day life span, the red cells are engulfed by macrophages of the reticuloendothelial system (RES) where the iron is extracted from the hemoglobin. Some of this iron may remain stored in the RES as ferritin or hemosiderin, but most is delivered to the plasma where it becomes bound to transferrin, completing the cycle. In the normal adult male, about 30 mg of iron completes the iron cycle each day. An additional small amount of iron, probably less than 2 mg, leaves the plasma each day to enter hepatic parenchymal cells and other tissues. Here, the iron is utilized for tissue

Fig 4-7 Concept of the control of iron absorption by the intestinal mucosa. The columnar epithelium of the small intestine regulates iron absorption. In the normal state, the mucosal cell contains iron supplied from body stores and this reduces the amount of iron that can be absorbed from the bowel. As a result, some iron remains in the gut lumen and is lost. Iron that enters the cell, but is not absorbed into the blood stream, also is lost when the columnar cell is sloughed at the end of its life span.

In iron deficiency, there is little to prevent entry of iron into the villous epithelial cells, nor is it retained there. It passes readily into the blood.

In iron-loaded subjects, the body iron that is incorporated into the epithelial cells is eventually lost as these cells are sloughed, but during the life span of the cells its presence inhibits the entry of iron into the cells. (From Crosby,<sup>324</sup> courtesy of the author and Grune & Stratton.)

heme proteins, such as myoglobin and the cytochromes. In the paragraphs to follow, each of the major components of the iron cycle and the factors governing the movement of iron from one to another will be discussed in greater detail.

#### Plasma Iron Transport

The plasma iron-binding protein, transferrin<sup>364</sup> ("siderophilin"), is a pink glycoprotein

with the electrophoretic mobility of a  $\beta_1$ -globulin. There is rather poor agreement as to its molecular weight, reported values ranging from 68,000 to 95,000.<sup>359</sup> With gel electrophoresis, a number of genetic transferrin variants have been identified, presumably differing from one another in amino acid sequence.<sup>392</sup> They are inherited in an autosomal, codominant fashion, and all appear to share the same important chemical and physiologic functions.

Transferrin is synthesized chiefly in the liver by the parenchymal cells,<sup>359,401</sup> but additional synthesis may occur in macrophages of lymphoid tissue and in such ectodermal glands as the submaxillary and mammary glands, as well as in the ovary and testis.<sup>401</sup> Several groups of investigators have labeled transferrin with <sup>131</sup>I in order to study its distribution and kinetics.<sup>304,322,359</sup> These studies show that the protein is about equally distributed between plasma and extravascular sites; exchange takes place between the two compartments at the rate of about 5% per hour. Transferrin turnover follows first-order

kinetics with a half-disappearance time of about 10 days. The sites and mechanism of catabolism have not been clearly delineated.

The concentration of transferrin in the plasma is about 2.5 g/l. More commonly, transferrin is quantified in terms of the amount of iron it will bind, a measure called the "total iron-binding capacity" (TIBC). In the normal subject, the plasma iron concentration is about 18  $\mu\text{mol/l}$  (100  $\mu\text{g/dl}$ ) and the TIBC is 56  $\mu\text{mol/l}$  (300  $\mu\text{g/dl}$ ). Thus, only about one third of the available transferrin binding sites are occupied. There is a diurnal variation in plasma iron concen-

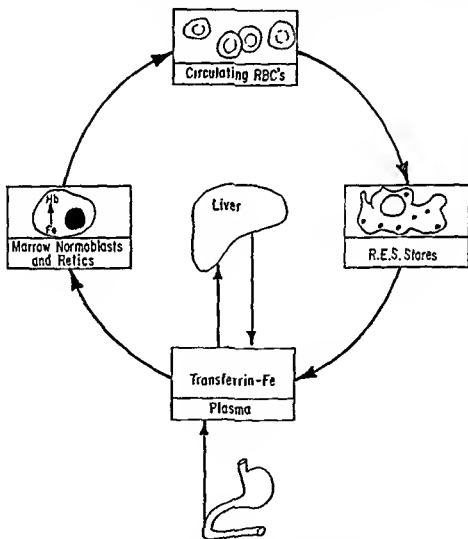

Fig 4-8. The iron cycle in man. Iron (Fe) travels from plasma to the marrow where it is incorporated into hemoglobin. It is then released with the mature red blood cells (RBC's) into the circulation. After a life span of about 120 days, the red cell is engulfed by cells of the reticuloendothelial system (RES). Here, the iron is extracted from hemoglobin and returned to plasma where it becomes bound to transferrin, completing the cycle.

tration, with highest values in the morning and the lowest in the evening. No diurnal variation occurs in TIBC. Data on normal values for plasma iron and TIBC are given in the Appendix (Table A-21), and expected variations in disease are discussed in Chapter 16.

Transferrin binds two molecules of trivalent (ferric) iron at spatially separated sites on the protein.<sup>359</sup> Most studies have indicated that the two binding sites have identical physical and chemical characteristics.<sup>359</sup> However, more recent observations with electron paramagnetic resonance, and also Mossbauer and optical difference spectroscopy, suggest that the two sites differ from one another.<sup>299, 302, 387</sup> Although the exact nature of the sites is not known, it is probable that three tyrosine and two histidine residues attach to the iron and that the tertiary configuration of the protein is essential to optimal binding.<sup>359</sup> One mole of bicarbonate is taken up and three moles of hydrogen ion are liberated for each mole of iron bound. The characteristic pink color of transferrin, with an absorption peak at a wavelength of 465 nm, is a function of the interaction between iron, bicarbonate, and the binding site. Under physiologic circumstances, the affinity of transferrin for iron is very great. The intrinsic binding constant is of the order of  $10^{36}$ , a value much higher than for other known iron chelating agents. Affinity of transferrin for iron can be decreased by lowering the pH or by reducing the iron to the divalent (ferrous) form. Other transition metals, such as copper, chromium, manganese, and cobalt, can be bound by transferrin,<sup>300</sup> but with much less affinity than iron.

The transferrin-mediated delivery of iron to red cell precursors imparts direction to the flow of iron. Unbound iron is not oriented toward a specific target<sup>333</sup>; instead, it leaves the plasma rapidly and becomes distributed to many tissues with no regard for their iron needs. The biologic importance of transferrin is illustrated by the findings in patients with congenital atransferrinemia,<sup>343, 351</sup> whose red cells had the morphologic stigmata of iron deficiency, but whose tissues were laden with iron. Thus, although iron continued to be

absorbed, it could not be provided to the developing normoblasts.

In the course of delivering iron to erythrocyte precursors, transferrin becomes transiently bound to the cells,<sup>357</sup> a phenomenon that to some degree is species specific.<sup>363</sup> Only cells that are capable of synthesizing hemoglobin bind transferrin. Thus, 75  $\mu$ g of transferrin are bound by 1.0 ml of reticulocytes (about 50,000 molecules of transferrin per cell), but only 0.6  $\mu$ g is bound by 1.0 ml of mature erythrocytes. Since the binding process could be inhibited by pre-incubation of the reticulocytes with trypsin or neuraminidase, and since bound transferrin was attached to "stroma" after hemolysis, it was proposed that there are specific receptor sites for transferrin located on the red cell membrane.<sup>357, 359</sup> It is thought that, after binding occurs, iron is released into the cell and apoferritin is liberated into the surrounding plasma. However, the possibility that both the iron and protein enter the cell has not been excluded completely.<sup>376</sup>

Fletcher and Huehns have proposed that the two transferrin iron-binding sites behave differently with respect to tissue iron transfer.<sup>339</sup> One site, designated "A," releases its iron preferentially to erythroblasts, whereas the "B" site releases its iron preferentially to other tissues, such as the liver. Although additional investigation is required before this idea can be accepted, some support for it has come from *in vitro*<sup>341</sup> and *in vivo*<sup>305</sup> studies.

The nature of the interaction between transferrin and the erythrocyte at the molecular level is not yet understood. The kinetics of the reaction(s) are similar to those of an enzymatic or a carrier-mediated reaction,<sup>362</sup> but no enzyme or carrier has been identified. There is indirect evidence that at least two distinct processes are involved: transferrin uptake, and release of iron from transferrin.<sup>376</sup> The first may represent passive attachment to (or diffusion across) the membrane since it requires little energy and is inhibited by agents like trypsin, which act primarily on the membrane.<sup>332</sup> The second appears to require an intact, mitochondrial electron-transport chain and can be inhibited

by a variety of agents that interfere with mitochondrial function. Reagents that react with sulfhydryl groups also inhibit the iron delivery process, but it is not clear whether they do so by affecting transferrin uptake<sup>376</sup> or iron release.<sup>332</sup>

The rate of entry of iron into normoblasts also is intimately related to heme biosynthesis.<sup>386</sup> The addition of free heme inhibits reticulocyte iron uptake *in vitro*. Furthermore, a decrease in intracellular free heme concentration induced by inhibitors of heme synthesis (eg, isoniazid) leads to increased iron uptake, and an increase in intracellular free heme induced by inhibitors of globin synthesis (eg, cycloheximide) has the opposite effect. These phenomena may reflect a feedback-inhibition system that regulates the supply of iron according to the needs of the cell for hemoglobin synthesis.

The transferrin system undoubtedly represents the most important pathway by which iron gains access to the red cell. However, an alternate route has been proposed on the basis of electron microscopic observations.<sup>308</sup> Bessis and Breton-Gorius described islands of normoblasts in bone marrow centered around large reticuloendothelial cells.<sup>308</sup> They consider these to be distinct anatomic units whereby normoblasts obtain iron as well as other essential building materials. The surface of the normoblast presents little invaginations that become tiny vacuoles penetrating the cytoplasm of the normoblast (Chapter 3, page 85). Small particles of cytoplasm of the central reticuloendothelial cells appear to be aspirated in this way, a process that Bessis and Breton-Gorius have termed "rhopheocytosis." Others have confirmed these findings and have presented evidence that the direction of movement is, as Bessis and Breton-Gorius proposed, from RE cell to normoblast.<sup>399</sup> The quantitative significance of this process is still to be determined.

#### Iron Metabolism within Normoblasts

The fate of iron after having entered the immature erythrocyte is known in broad outlines, but much remains to be learned about

the biochemical steps and intermediates in the process. In the normal subject, about 80 to 90% of the iron that enters the cell ultimately is taken up by mitochondria and incorporated into hemoglobin. Most of the remainder is accounted for as ferritin,<sup>369,388,411</sup> the chemical nature of which will be discussed in a later section (page 162). The presence of ferritin in erythrocytes may sometimes be detected by means of the Prussian blue reaction.<sup>329,330</sup> Normoblasts with Prussian blue-positive (siderotic) granules are called *sideroblasts*, and, if the granules persist after denucleation, the mature cells are called *siderocytes*. In the normal person, about half of the normoblasts are sideroblasts, each containing less than five small granules.<sup>330</sup> By electron microscopy (see pages 33, 87), these "normal" siderotic granules are seen to be aggregations of ferritin, often surrounded by a membrane ("siderosomes").<sup>308,329</sup> Isolated molecules of ferritin, not surrounded by a membrane, may also be seen by means of electron microscopy, but not with light microscopy.

Another kind of sideroblast, the "ringed" sideroblast, is found only under pathologic circumstances<sup>312</sup> ("sideroblastic anemias," Chapter 18). In the ringed sideroblast, the siderotic granules form a full or partial ring around the nucleus, and on electron microscopy the iron is found to be deposited in mitochondria.<sup>368</sup> The chemical form of the mitochondrial iron is not known, but it does not appear to be ferritin.

The two kinds of siderotic granules can be induced experimentally in swine.<sup>329</sup> Vigorous phlebotomy leads to the formation of siderocytes that are reticulocytes containing ferritin aggregates ("R-S cells"). Production of vitamin B<sub>6</sub> deficiency leads to siderocytes characterized by iron-laden mitochondria. The spleen is required for removal of the iron-laden mitochondria, but not of the "normal" cytoplasmic ferritin aggregates. The latter are removed by solubilization and extrusion of ferritin into the surrounding media, a process requiring active cellular oxidative metabolism.<sup>329,359</sup> Variation in numbers of sideroblasts and siderocytes in disease is discussed in Chapters 16 and 18.

In the red cell, ferritin appears to function as a component of a mechanism by which unneeded iron can be temporarily stored and later excreted. This function may be inferred from two observations: (1) once iron is incorporated into ferritin it does not appear to be available for heme synthesis,<sup>388,411</sup> and (2) as noted above, the cell is able to discharge ferritin into the surrounding plasma. Not excluded, however, is the possibility that the ferritin iron may be made available to the cellular hemoglobin-synthesizing apparatus under special pathologic or physiologic circumstances.

Intracellular iron compounds other than heme and ferritin are presumed to exist, but have not been identified. One proposed intracellular iron-transport protein<sup>347</sup> was later acknowledged to be an artifact.<sup>388</sup> There is fragmentary evidence for an iron compound of small molecular weight to which iron is attached as it passes from transferrin to hemoglobin.<sup>369,388,411</sup> Chelates of iron with ATP or ADP possess many of the properties expected of such a compound,<sup>312,369,398</sup> but iron citrate<sup>301</sup> and other soluble iron chelates also are candidates for this role. Furthermore, the inhibition of reticulocyte heme synthesis by the ferrous chelating agent, bipyridine,<sup>388</sup> suggests that iron may exist, at least transiently, in ionic form.

### Iron Metabolism in the Reticuloendothelial System

At the end of its life span, the erythrocyte is engulfed by reticuloendothelial (RE) cells. These cells acquire most, and possibly all, of their iron by this means. They probably do not accept measurable amounts of iron from transferrin,<sup>335,359</sup> although a contrary view was suggested by one study.<sup>367</sup> Within the RE cell, the erythrocyte membrane is broken, and hemoglobin iron is oxidized to the trivalent state, forming methemoglobin (page 105). In this form, the heme and globin dissociate from one another relatively easily. Then, iron is liberated from heme, a reaction that requires an enzyme, microsomal heme oxygenase. This reaction is discussed in more

detail in relation to the metabolism of bile pigment (page 208).

The RE system is the principal source of supply of iron to the plasma. In order to meet a variable demand for iron, the RE system maintains a sizable storage pool in the form of ferritin and hemosiderin. Under equilibrium conditions, ie, when the amount of iron that enters the RE cell approximates that which leaves it, there is relatively little interchange between the newly liberated iron and the storage forms.<sup>380</sup> Instead, iron from recently destroyed erythrocytes passes quickly through the RE cell and is presented to the plasma at the cell surface. The intermediate iron compounds in this process, if any, are not known. However, at the cell-plasma interface, the iron probably is in the form of ferrous ion, and it must be oxidized in order to be bound to transferrin. The ferrous oxidation (ferroxidase) reaction is catalyzed by the plasma copper protein, ceruloplasmin.<sup>239,243,244</sup> (page 150).

In non-equilibrium situations, iron either enters or leaves the stores. When the red cell mass is expanding and erythrocytes are being produced more rapidly than they are being destroyed, iron is mobilized from RE stores. The amount of iron leaving the RE cell then exceeds that which enters. When red cell destruction exceeds production, iron is deposited in stores, and the amount of iron entering the RE cell exceeds that which leaves. It is apparent that mechanisms must exist for coupling the rate at which iron leaves the RE cell to the rate of red cell production. The nature of the control mechanism remains unknown.

The two iron storage compounds are ferritin and hemosiderin. The ferritin molecule is roughly spherical in shape and consists of a protein shell surrounding a ferric hydroxyphosphate core.<sup>319</sup> The protein portion (apoferritin) has a molecular weight of about 460,000 and is probably made up of 24 polypeptide subunits, each with a molecular weight of about 18,500. When fully saturated with iron, ferritin has a molecular weight near 900,000 and contains about 5000 iron atoms per molecule (about 23% of the dry weight).

The iron is in a trivalent, polymerized form with the probable subunit structure of  $(\text{FeOOH}_8) \cdot (\text{FeO} \cdot \text{PO}_3\text{H}_2)$ .

The protein structure of ferritin appears to be organ specific. Hepatic ferritin differs from splenic ferritin in electrophoretic mobility and in tryptic peptide "fingerprint" pattern.<sup>321</sup> Furthermore, two distinct ferritins can be extracted from bone marrow.<sup>340</sup> One of these ("anabolic" ferritin) is of red cell origin, and its iron is derived from transferrin. The other ("catabolic" ferritin) is of RE origin, possibly identical to splenic ferritin, and derives its iron from hemoglobin. It seems likely that the various ferritins have functional as well as structural differences, but these remain to be demonstrated.

In a variety of organs, the synthesis of apoferritin is stimulated by exposure to iron, both *in vivo* and *in vitro*.<sup>319</sup> This phenomenon is blocked by inhibitors of protein synthesis (eg, cycloheximide), but not by inhibitors of RNA synthesis (eg, actinomycin D).<sup>319,371</sup> One would presume, therefore, that this effect of iron occurs at the translational level of protein synthesis. Possibly, accumulation of small amounts of apoferritin inhibits further polyribosomal synthesis, but when iron is added and ferritin is formed, the inhibition is released.

Two model mechanisms have been proposed for the combination of iron and apoferritin to form ferritin. In the conventional model, apoferritin is visualized as a pre-formed, hollow sphere with an external diameter of 12.0 nm and an internal diameter of 7.0 nm. Iron enters the sphere as ferrous ion; it is oxidized to the ferric form by molecular oxygen and is deposited irregularly and in variable amounts until saturation is achieved. This model is supported by x-ray diffraction studies.<sup>336</sup> In the second proposed model<sup>381</sup> the 7.0-nm iron core is pre-formed by polymerization of a ferric chelate. Then, apoferritin subunits form around this core to complete the molecule. The *in vitro* incorporation of transferrin iron into ferritin requires both a reducing agent, of which ascorbate is the most effective, and an iron chelating agent, such as ATP.<sup>372</sup> The reducing agent

probably functions, at least in part, to liberate iron from transferrin. The chelating agents may facilitate passage of iron through biologic membranes. Thus, these observations may or may not be applicable to situations in which the iron source is not transferrin, as in the gut mucosa or in the RE cell.

Two views also exist regarding the mechanism of mobilization of iron from ferritin. In the first, mobilization is considered to occur by reduction of the iron to the ferrous form, thereby releasing it from the protein. A variety of reducing agents can produce this effect *in vitro*. A possible *in vivo* reducing system, namely, xanthine oxidase, has been implicated in ferritin iron release in a series of studies by Mazur et al.<sup>370</sup> The second proposed mechanism postulates that iron is mobilized from ferritin by low molecular-weight chelating agents, without the necessity for reduction to the ferrous form.<sup>382</sup>

Hemosiderin was formerly distinguished from ferritin on the basis of solubility and the Prussian-blue reaction. Ferritin was considered to be soluble and Prussian-blue negative; hemosiderin, insoluble and Prussian-blue positive. Now that the ferritin molecule can be recognized by electron microscopy (page 33), these distinctions are no longer clear-cut. For example, a number of Prussian-blue positive, insoluble granules have been shown to contain ferritin.<sup>308,329,393</sup> On the basis of physical and chemical characteristics described in the previous paragraphs it is becoming clear that ferritin is a relatively homogeneous substance. By comparison, hemosiderin is a less precisely definable entity,<sup>390</sup> generally differing from ferritin in having a higher iron-to-protein ratio as well as being less soluble in aqueous solutions.

In most instances, hemosiderin appears to be derived from ferritin. Ferritin polymers of various sizes may represent intermediates between ferritin and recognizable forms of hemosiderin.<sup>409</sup> The simplest form of hemosiderin is a dense aggregate or crystal of ferritin, which may or may not be enclosed by a membrane.<sup>350</sup> It has been found that the proportion of iron in hemosiderin is variable (24 to 45%), but usually is much greater than

that in ferritin (16 to 23%). Thus, it seems likely that, in the formation of hemosiderin, protein is lost by denaturation or proteolysis. Morphologic evidence is consistent with this view.<sup>337</sup> As the protein is lost, the iron units acquire the characteristics of  $\text{Fe}_2\text{O}_3$  units. It has also been shown that structures that have the histochemical characteristics of hemosiderin may be very complex and contain lipids, porphyrins, and other substances in addition to iron.<sup>390</sup>

From a physiologic viewpoint, hemosiderin appears to represent a more stable and less available form of storage iron than ferritin.<sup>377,396</sup> Newly deposited or newly mobilized iron enters or leaves the ferritin compartment. Only after prolonged storage or continued mobilization does the hemosiderin compartment change in size.

#### Iron Metabolism in Other Tissues

Iron is required in small amounts by many tissues for the synthesis of non-hemoglobin, iron-containing enzymes and proteins, among which are the cytochromes, catalase and myoglobin. It is presumed that most of these tissues acquire their iron from transferrin<sup>359</sup> and there is indirect evidence for the existence of receptor sites analogous to those on erythrocytes.<sup>338</sup> Of the non-erythrocyte iron pathways, the exchange with the *hepatic parenchymal cell* seems to be the largest and has been the most extensively studied. Normally, about 5% of iron leaving plasma is accounted for by this pathway.<sup>335,359</sup> This fraction increases greatly when transferrin saturation increases or when erythropoiesis is depressed. The *placenta* also accepts iron from transferrin, and may do so even at relatively low plasma iron levels, thus effectively competing with the maternal erythroid marrow.<sup>359,365</sup> This function appears to be independent of fetal influences and is a property of the placental cell itself.<sup>368</sup> Under normal circumstances, efficient transfer to the fetus occurs, but some iron is stored as ferritin and hemosiderin. The *gut* also accepts iron from transferrin, and this pathway may have a regulatory function in iron absorption (page 157).

*Skeletal muscle* utilizes iron for myoglobin synthesis and also maintains an iron storage pool that, although large, is not easily mobilized for use by other tissues.<sup>324</sup>

#### Ferrokinetics<sup>311,335,394,385</sup>

It is possible to measure some of the rates at which iron moves around the iron cycle by using radioactive tracers. In the usual ferrokinetic study, transferrin is labeled with <sup>59</sup>Fe. The tracer is then monitored as it moves from the plasma to the bone marrow and into the circulating red cells. Since the kinetics of iron are intimately related to hemoglobin synthesis, such a study makes it possible to assess rates and sites of erythropoiesis, and to evaluate "ineffective" and "effective" erythropoiesis (Chapter 13).

<sup>59</sup>Fe is injected directly as ferrous citrate or is first bound to transferrin by incubation with fresh plasma. Serial samples of blood are taken at frequent intervals during the first several hours and daily thereafter. These are analyzed for plasma and red cell radioactivity, plasma iron concentration, and VPRC. For some calculations, a separate determination of plasma volume is made (page 121), or it may be calculated from the extrapolated zero-time plasma radioactivity and the total injected radioactivity. The basic measurements calculated from these data are given in Table 4-5.

The plasma iron transport rate (PIT) is a measure of the rate at which iron leaves the plasma. It may be expressed either as a total daily rate (ie, mg of iron per day) or as a rate per volume (dl) of blood. The latter mode of expression has the two advantages of obviating the need for determining plasma volume and of incorporating a built-in correction for body size. It assumes, however, that the blood volume is approximately normal and should not be used if there are clinical reasons to doubt this assumption. The PIT is generally considered to be a good index of "total" erythropoiesis, whether "effective" or "ineffective." It correlates well with the total nucleated red cell mass and with the rate of red cell production induced by phlebotomy.<sup>335</sup> However, when erythro-

Table 4-5. Basic Ferrokinetic Measurements

Measurement	Calculation	Average Normal Value
$t_{1/2}$	Graphically, from semilogarithmic plot of plasma radioactivity disappearance	86 minutes

		-or-
		0.56 mg/day/dl blood
MTT	Graphically, from a semilogarithmic plot the time at which $100 - \text{RCU} = 50\%$	3.5 days

Abbreviations  $t_{1/2}$ , plasma Fe half-disappearance time; PIT, plasma iron transport rate; RCU, red blood cell utilization; EIT, erythrocyte iron turnover rate; MTT, marrow transit time; VPRC, volume of packed red cells.

poiesis is reduced, or when the degree of transferrin saturation is high, the interpretation of PIT is complicated by transfer of iron to tissues other than marrow.

The erythrocyte iron turnover rate (EIT) is a measure of the rate at which iron moves from marrow to circulating red cells. Like PIT, it may be expressed as a total daily rate or as a rate per dl of blood, and the same advantages and disadvantages of the two modes of expression apply. It is an index of "effective" erythropoiesis and correlates well with an appropriately corrected reticulocyte index<sup>389</sup> (Chapter 20, page 731).

The observation that red cell iron utilization (RCU) is usually less than 100%, and that there is, therefore, a discrepancy between PIT and EIT, indicates that a proportion of the iron leaving plasma does not make its appearance in circulating red cells. There are several possible fates for this "nonutilized" iron. It may enter non-erythroid tissues; it may be lost with hemoglobin when normoblast denudation occurs; it may be lost with intramedullary destruction of defective red cells ("ineffective" erythropoiesis); and, fi-

nally, it may enter one of several "reflux" pathways, to be discussed further below. When RCU is reduced and there is a relatively large difference between PIT and EIT, one of these pathways accounts for a larger than normal proportion of plasma iron turnover.

The marrow transit time (MTT) may be used to evaluate erythropoietin response. In general, this value decreases in proportion to the degree of erythropoietic stimulation. In situations characterized by an appropriate marrow response to anemia, there is a predictable relation between VPRC and MTT (Fig. 4-9).

In addition to the above determinations on blood specimens, it is possible to monitor iron movements within the body by surface counting over the liver, spleen, and sacrum (marrow). This procedure may be particularly useful in detecting extramedullary hematopoiesis.

Variations of ferrokinetic measurements in representative disease states are illustrated in Figure 4-10 and Table 4-6. Ferrokinetic patterns in other disorders are discussed in the

Fig 4-9 Relation of marrow transit time to volume of packed red cells (hematocrit) in normal subjects (From Finch et al.<sup>335</sup> courtesy of the authors and Medicine)

chapters dealing with specific disease entities. When erythropoiesis is reduced, as in hypoplastic anemia, the PIT may be normal or only slightly reduced, but RCU and EIT are greatly reduced. Furthermore, iron appears early in the liver and is retained there. When erythropoiesis is accelerated in hemolytic anemia, both PIT and EIT are increased and

radioactivity accumulates at the sites of destruction, ie, the spleen or liver. In states of ineffective erythropoiesis, eg, thalassemia major, PIT is greatly increased, RCU is reduced, and EIT is relatively normal. There may be early iron uptake over organs in which the defective cells are destroyed.

The above ferrokinetic measurements are useful for clinical and investigational purposes, but they must be considered only approximations of the parameters that they purport to measure. The calculations are based on the incorrect assumption that iron leaves plasma at a single, exponential rate. The early part of the plasma disappearance curve does, in fact, approximate a straight line on semilogarithmic paper. However, after several hours, there is a significant change in the slope of the line until another, much slower, exponential disappearance rate is established (Fig. 4-11). This phenomenon is explained by the return to plasma of about 35% of the iron that leaves it.<sup>335</sup> To account for this reflux, various models have been

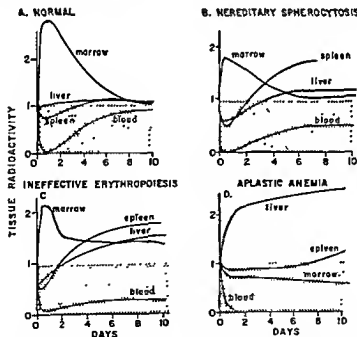

Fig 4-10 Pattern of radioactivity in blood and over sacrum (marrow), liver, and spleen during a ferrokinetic study. Representative data from patients with four conditions are presented. Compare with Table 4-6 (From Finch et al.<sup>335</sup> courtesy of the authors and Medicine)

**Table 4-6. Ferrokinetic Data in Representative Clinical Situations**<sup>310,335</sup>

	$T_{1/2}$ (min)	$PIT$ (mg/day/dl)	$RCU$ (%)	$EIT$ (mg/day/dl)
Normal	86	0.7	80	0.56
Hypoplastic anemia	267	0.45	23	0.10
Hemolytic anemia (hereditary spherocytosis)	24	3.42	57	1.87
Ineffective erythropoiesis (thalassemia major)	21	6.87	18	1.24

Values are means

proposed, of which the most widely used has been that of Pollycove and associates.<sup>385</sup> Central to their model is a proposed "labile iron pool," about 80 mg in size, that is interposed between the plasma and red cell pools and from which reflux of iron to plasma occurs. It has been impossible to demonstrate the existence of such a pool, however, and formidable evidence against the model has

been presented.<sup>335</sup> The reflux may be divided into two components, a rapid reflux of 5 to 10% with a  $t_{1/2}$  of about eight hours and a slower reflux of 25% of about eight days. The first may represent the exchange of transferrin with the extravascular space, and the second is probably a by-product of erythropoiesis. It is possible to correct the various ferrokinetic measures for reflux and thereby improve their accuracy. As yet, however, such correction factors have not been employed routinely, and the improved accuracy may not be necessary for most clinical purposes.

## Hemoglobin Structure and Synthesis

Hemoglobin is the name applied to the oxygen transport protein of erythrocytes. Since it accounts for about 90% of the dry weight of the mature erythrocyte, a major proportion of the biosynthetic activity of the developing normoblast must be devoted to its production. Hemoglobin is a conjugated protein with a molecular weight near 64,500. About 96% of the molecule is protein (globin) and the remainder is a highly colored prosthetic group, heme, a complex of iron and protoporphyrin (Fig. 4-12). An optimal rate of hemoglobin synthesis requires the proper functioning of three complex metabolic pathways, corresponding to each of the three structural components of hemoglobin. One of these, the iron metabolic pathway, has been

**Fig. 4-11.** The plasma radioiron disappearance curve. The curve can be resolved into two components. The initial, rapid disappearance (component A) is used for routine ferrokinetic calculations. The second, slower component results from several reflux pathways described in the text. (From Finch et al.<sup>335</sup> courtesy of the authors and Medicine)

Fig. 4-12. Chemical structure of heme and its manner of union with globin to form hemoglobin. The carbon atoms derived from the alpha carbon of glycine are represented by • those supplied from the methyl carbon of acetate by A, those derived from the carboxyl group of acetate by x. The unmarked carbons are those which are derived from either the methyl carbon atom of acetate or from the carboxyl atom (Prepared by Dr. G. E. Cartwright.)

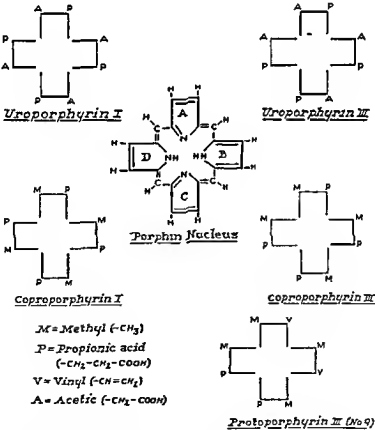

Fig. 4-13. Structural formula of the porphyrin nucleus and diagrammatic representation of some naturally occurring porphyrins (Prepared by Dr. G. E. Cartwright.)

discussed on preceding pages. The pathways for the biosynthesis of heme and of globin will be discussed in this section.

## Heme

In order to understand heme structure and synthesis, the terminology applied to the porphyrins must be appreciated.<sup>447-463</sup> Porphyrins are tetrapyrroles. The four pyrrole rings are united by four methene ( $=C-$ ) bridges, thus forming the porphyrin ring. This is a resonant structure and is characterized by distinctive properties of color and fluorescence. The simplest porphyrin, porphin (Fig. 4-13), does not occur in nature; in the natural compounds, eight of the hydrogen atoms have been replaced by certain substituent groups, namely, methyl ( $-CH_3$ ), vinyl ( $-CH=CH_2$ ), acetic acid ( $-CH_2-COOH$ ), or propionic acid ( $-CH_2-CH_2-COOH$ ). The porphyrin in hemoglobin, protoporphyrin, has only two carboxyl ( $-COOH$ ) groups. In protoporphyrin, eight hydrogen atoms of the porphin nucleus are replaced by four methyl, two vinyl, and two propionic acid groups (Fig. 4-13). Normal feces contain small amounts of a tetra-carboxylated porphyrin, which Fischer called coproporphyrin. Both coproporphyrin and protoporphyrin are soluble in nonpolar solvents, but are relatively insoluble in water at physiologic pH. The third important porphyrin compound is uroporphyrin, so named because it was first isolated from urine. Uroporphyrin differs from coproporphyrin in that the four methyl groups are replaced by acetic acid side chains (Fig. 4-13). This octa-carboxylated acid is water soluble and is insoluble in ether and most other organic solvents.

In theory, there are four possible ways in which the two types of side chains in coproporphyrin and uroporphyrin can be arranged. The isomers that result are designated by roman numerals, I, II, III, and IV. Only types I and III are found in nature, and only type III porphyrins can be utilized for heme synthesis. In type I porphyrins the substituent groups alternate regularly, as shown in

Figure 4-13; in type III, one pair is asymmetrical. When three types of side chains are present, as in protoporphyrin, the number of possible isomers is 15. The protoporphyrin isomer in hemoglobin is designated protoporphyrin 9, type III.

The propionic acid side chains of protoporphyrin may possibly function in the ionized form to orient the heme and help attach it to globin. The methyl groups protect the positions at which they are attached. The vinyl groups are required to make possible the insertion of iron into the porphyrin ring.<sup>451,456</sup>

## Biosynthesis of Heme<sup>451,465,467</sup> (Fig. 4-14)

From isotope studies *in vivo*,<sup>487</sup> by incubation of labeled precursors with avian erythrocytes<sup>479</sup> and mammalian reticulocytes,<sup>460</sup> and from studies of the microorganism, *Rhodospseudomonas spheroides*,<sup>465</sup> a clear picture has been gained concerning steps in the synthesis of heme. The first precursor of heme,  $\delta$ -aminolevulinic acid (ALA), is derived from the condensation of the 2-carbon amino acid, glycine, and "activated" succinic acid (succinyl CoA).<sup>459</sup> The latter can be formed in several ways. In the tricarboxylic acid (Krebs) cycle, its normal precursor is  $\alpha$ -ketoglutarate. Other metabolic sources of succinyl CoA include (1) a reaction of succinate with CoA and guanosine triphosphate in the presence of the enzyme succinyl CoA synthetase; (2) the transfer of CoA from acetoacetyl CoA to succinate, a reaction catalyzed by acetoacetyl CoA: succinyl CoA transferase; and (3) valine and isoleucine, which are metabolized to succinyl CoA via propionyl CoA and methylmalonyl CoA.<sup>446</sup> The relative importance of these various sources in heme biosynthesis remains to be determined.

The condensation of glycine with succinyl CoA takes place in the presence of the enzyme, ALA synthetase.<sup>448,464</sup> The level of this enzyme, which is the most important rate-limiting factor in the heme biosynthetic pathway, is controlled by induction and repression of enzyme synthesis.<sup>450,455</sup> Certain

Fig 4-14 Chemical steps in the biosynthesis of heme. For abbreviations see text

chemicals, such as allylisopropylacetamide, bring about excessive enzyme induction, thereby causing a type of porphyria. Perhaps of more physiologic significance is the observation that certain sex hormones and their derivatives may behave as inducers.<sup>450,468</sup> Glucose and high-carbohydrate diets block induction of the enzyme,<sup>482</sup> perhaps by promoting conjugation of the inducers with glucuronide,<sup>450</sup> and hence may be used in therapy of porphyria (Chapter 32). Heme, the end product of the pathway, represses synthesis of ALA synthetase.<sup>458</sup> Another factor that affects the rate of this reaction is feedback

inhibition<sup>444</sup>; heme not only represses enzyme synthesis but also inhibits the activity of enzyme already formed. Heme appears to accomplish this inhibition by forming a coordination complex between its iron atom and the enzyme.<sup>470</sup> Thus, because of its repressive and inhibitory effects, any accumulation of heme leads to a reduced rate of ALA synthesis. Conversely, if heme is removed rapidly by union with globin, ALA synthesis is stimulated.

It is possible that the first product of the ALA synthetase reaction is  $\alpha$ -amino- $\beta$ -keto-adipate,<sup>478</sup> an unstable compound that is rap-

idly decarboxylated to ALA. Synthesis of ALA requires the participation of two vitamins, pyridoxine, in the form of pyridoxal phosphate, and pantothenic acid, as a component of CoA.<sup>474</sup> It has been suggested that iron is also a cofactor in the reaction<sup>443</sup>; however, other observations indicate that the effect of iron is explained by augmentation of enzyme synthesis.<sup>481</sup>

In the next step, two ALA molecules are joined in the presence of the enzyme,  $\delta$ -aminolevulinic dehydrase ( $\Delta$ -ALA-DH),<sup>448,485</sup> to form porphobilinogen (PBG), a monopyrrole that carries acetic acid and propionic acid side chains.<sup>452</sup> The enzyme requires sulfhydryl groups for its activity and therefore is inhibited by lead and stabilized by glutathione.

In the succeeding step, four PBG molecules condense to form uroporphyrinogen III.<sup>442,453,466</sup> This reaction requires two enzymes, uroporphyrinogen synthetase (porphobilinogen deaminase, PD) and uroporphyrinogen III cosynthetase (uroporphyrinogen isomerase, UI). Many mechanisms have been proposed to explain the manner in which uroporphyrinogen III is formed.<sup>472</sup> It is probable that, in the presence of uroporphyrinogen synthetase, PBG is converted to an intermediate compound. In the absence of uroporphyrinogen III cosynthetase, this intermediate spontaneously becomes converted to uroporphyrinogen I, but, in the presence of the cosynthetase, uroporphyrinogen III is formed. Several structures for the hypothetical intermediate have been proposed,<sup>442,467,472,486</sup> but none has been proved.

Uroporphyrinogen and other porphyrinogens differ chemically from their corresponding porphyrins in that they have six additional hydrogen atoms in the tetrapyrrole ring (compare Figs. 4-13 and 4-14). With this alteration, the ring does not resonate, and therefore the porphyrinogens are colorless and do not fluoresce. In the presence of light and oxygen, spontaneous oxidation of porphyrinogens to porphyrins occurs. Since porphyrins cannot be utilized in heme synthesis, the porphyrinogens are considered to be the

true metabolic intermediates in the pathway.<sup>442</sup>

Coproporphyrinogen III is formed from uroporphyrinogen III by decarboxylation of the four acetic acid side chains. The conversion is catalyzed by the enzyme uroporphyrinogen decarboxylase (UD).<sup>452,453,469</sup> It is probable that the four carboxyl groups are removed sequentially and that seven, six, and five carboxyl porphyrinogens are intermediates in the reaction.

Conversion of coproporphyrinogen III to protoporphyrin requires a mitochondrial enzyme (or system of enzymes) called coproporphyrinogen oxidase (COX) or coproporphyrinogenase.<sup>441,451,454,473</sup> In mammalian tissues and aerobic bacteria, the reaction requires molecular oxygen as a hydrogen acceptor, and it is probable that a tricarboxylic porphyrinogen and protoporphyrinogen are reaction intermediates.

The last step in heme synthesis is catalyzed by an enzyme, called heme synthetase<sup>449,456,475</sup> or ferrochelatase,<sup>462,477</sup> that is located on the inner mitochondrial membrane.<sup>455</sup> In this step, ferrous iron is inserted into the protoporphyrin ring. The reaction is enhanced *in vitro* by reducing agents, such as cysteine, glutathione, or ascorbate, that apparently act by maintaining the iron in the reduced state. Possibly because of the opposite effect, the reaction is inhibited by aerobic conditions. A phospholipid may be a cofactor in the reaction.<sup>456</sup>

The biosynthesis of heme bears a peculiar relation to mitochondria. The first step and the last two steps are mitochondrial, whereas the intermediate steps occur in the extramitochondrial cytoplasm. Consequently, as they mature and their mitochondria degenerate, erythrocytes lose the ability to form ALA and to convert coproporphyrinogen III to heme. However, they retain the ability to convert ALA to coproporphyrinogen.

#### Porphyrins in Erythrocytes, Urine, and Stools<sup>447,477</sup>

In red cells, in addition to the protoporphyrin incorporated into heme, free proto-

porphyrin (FEP) and free coproporphyrin (FEC) are found in small amounts.<sup>476</sup> (For normal values, see Appendix, Table A-7.) The concentration of FEP increases when protoporphyrin is not utilized efficiently for heme synthesis,<sup>475</sup> as in iron deficiency,<sup>463</sup> the anemia of chronic disorders, lead intoxication, and certain sideroblastic anemias<sup>461</sup> (Chapters 16, 17, and 18). In persons with untreated pernicious anemia, low or low normal values are found. The concentration of FEC correlates with the reticulocyte count.<sup>476,483</sup> Thus, in hemolytic anemia, a relatively marked increase in FEC occurs although FEP is only moderately elevated.

Coproporphyrin and uroporphyrin, formed as by-products of heme synthesis, are excreted into the urine and stools.<sup>457,477</sup> (For normal values see Appendix, Table A-8.) Approximately half of the freshly passed porphyrins are excreted as the porphyrinogen. Increased urinary coproporphyrin may be found in association with lead poisoning, liver disease, and hemolytic anemia.<sup>484</sup> Fecal coproporphyrin is increased in patients with hemolytic anemia and decreased in those with liver disease. The ratio of urinary to fecal excretion of coproporphyrin appears to be related to hepatic function.

The porphyrias are a group of disorders in which great excesses of porphyrins and porphyrin precursors are excreted. These diseases are discussed in Chapter 32.

### Globin

From the standpoint of protein structure, there are several normal hemoglobins. Hemoglobin A or adult hemoglobin comprises 96 to 98% of the hemoglobin in adults. Most of the remainder is a structurally different hemoglobin called hemoglobin A<sub>2</sub>. In fetal life and in early infancy the predominant hemoglobin is fetal hemoglobin or hemoglobin F. During the first year of life, hemoglobin F is gradually replaced by hemoglobins A and A<sub>2</sub>, so that the former constitutes less than 1% of the hemoglobin of adults. Other normal hemoglobins (Gower I, II) are found only in the embryo (Chapter 2).<sup>508</sup>

All of the normal hemoglobins contain two pairs of polypeptide chains, and to each chain is attached one heme group. In hemoglobin A, the polypeptide chains of one pair are designated *alpha* ( $\alpha^A$ ) chains, and those of the other pair are called *beta* ( $\beta^A$ ) chains. This structure is signified by the formula,  $\alpha_2^A\beta_2^A$ . Fetal hemoglobin contains a pair of  $\alpha^A$ -chains identical to those found in hemoglobin A, but the chains of the second pair differ and are called *gamma* ( $\gamma^F$ ) chains; thus, hemoglobin F is designated  $\alpha_2^A\gamma_2^F$ . Hemoglobin A<sub>2</sub> contains a pair of  $\alpha$ -chains and a pair of *delta* ( $\delta^{A_2}$ ) chains and is designated  $\alpha_2^A\delta_2^{A_2}$ . The embryonic hemoglobin, Gower II, has the structure  $\alpha_2^E\zeta_2$ . Hemoglobin A<sub>2</sub> can be separated from hemoglobins A and F and quantified by means of a variety of electrophoretic or chromatographic procedures.<sup>504,516,523</sup> Many routine electrophoretic procedures do not distinguish hemoglobin F from A, but separation can be accomplished at pH 6.0 in agar gel.<sup>521</sup> More commonly, hemoglobin F is detected and quantified by its ability to resist denaturation in alkaline reagents (the "alkaline denaturation test," page 808).

Additional heterogeneity of normal hemoglobin has been observed. A fast-moving fraction (hemoglobin A<sub>3</sub>) that is detected by starch block electrophoresis is probably the same as fraction A<sub>1</sub> found on chromatography<sup>524</sup> (Fig. 4-15). These fractions contain a mixture of hemoglobins, of which some appear to be artifacts of storage or preparation, but others occur in vivo and may change in concentration with disease.<sup>509</sup> Although the exact nature of all of these hemoglobins is not known, most appear to be due to acquired alterations in the  $\beta^A$ -chain.<sup>501,509</sup> Still further heterogeneity results from genetic variations in hemoglobin structure, as discussed in Chapter 24.

### Structure of Globin<sup>513</sup>

The  $\alpha^A$ -,  $\beta^A$ -,  $\gamma^F$ -, and  $\delta^{A_2}$ -chains differ from one another in protein structure. In describing this structure, use will be made of a terminology that recognizes four different aspects of structure. These are: (1) primary

Fig. 4-15 Column chromatography of hemoglobin A on IRC-50 (method of Clegg and Schroeder, Developer No 5 used). The main component  $A_{III}$  corresponds to the Hb- $A_1$  demonstrated by starch-block electrophoresis.  $A_{IIIc}$  corresponds to Hb- $A_2$ , and  $A_{II}$  corresponds to  $A_3$ . (Courtesy of Dr. Robert L. Hill)

structure, or the sequence of amino acids, (2) secondary structure, which describes the organization of amino acids into helices stabilized by hydrogen bonds between the CO and NH groups of adjacent coils,<sup>517</sup> (3) tertiary structure, which refers to the manner in which the polypeptide chains are folded to form a three-dimensional, spherical unit stabilized by hydrophobic Van der Waals forces, and (4) quaternary structure, or the way in which several polypeptide chains join to form a single molecule.

It is now possible to state the exact primary structure of all four normal hemoglobin chains<sup>513</sup> (Table 4-7). The elucidation of this complex information required the application of a variety of sophisticated biochemical maneuvers that can be described here only superficially (for methodologic details, see ref 506). First, the chains were separated from one another in 8M urea solutions and isolated by counter-current distribution or chromatography. Then they were digested with trypsin to form a series of smaller peptides. These in turn were isolated by peptide-mapping ("fingerprinting") or by chroma-

tography (Chapter 24, page 810). Finally, the amino acid sequence of each peptide was determined chemically.

In spite of the differences in the primary structure of the chains, their secondary structures are remarkably similar. There are eight helical segments in each, and these helices are designated by the letters A through H<sup>519</sup> (Table 4-7). The helices are of nearly identical length in all four normal chains except for the D helix, which contains seven amino acids in the  $\beta$ -,  $\gamma$ -, and  $\delta$ -chains, but only two amino acids in the  $\alpha$ -chain. The helices make up about 75% of the molecule. Interspersed between them are seven non-helical segments: NA, AB, CD, EF, FG, GH, and HC. This arrangement is important structurally because the helices are relatively rigid and linear whereas the non-helical segments allow bending.

A given amino acid in a polypeptide chain may be denoted either by its sequential number or by a helical number. In the sequential system, the N-terminal amino acid is assigned the number 1, and each succeeding amino acid receives the next higher number until the

C-terminal end is reached. With this system, amino acids are numbered from 1 to 141 in the  $\alpha$ -chain and from 1 to 146 in the  $\beta$ -,  $\gamma$ -, and  $\delta$ -chains. In the newer helical system, each amino acid is designated by a letter and a number which indicate the helix and the position in the helix, respectively. The helical system is gradually gaining favor because it illustrates the homology between chains and has more structural significance. For example, the histidine to which heme attaches is amino acid #87 in the  $\alpha$ -chain and #92 in the  $\beta$ -,  $\gamma$ -, and  $\delta$ -chains; the helical designation for this histidine is the same in all the normal chains, namely, F8.

The tertiary and quaternary structures of hemoglobin have been studied by x-ray diffraction techniques, especially by Perutz and his coworkers.<sup>519</sup> In aqueous solutions and in crystals, the polypeptide chains assume a structure in which the polar amino acids are presented to the molecular surface where they interact with water, rendering the molecule soluble. The groups directed toward the inner core of the molecule are all nonpolar, and the hydrophobic (Van der Waals) bonding that occurs between them makes the structure stable. The resulting, roughly spherical, tertiary structure is similar for all the normal hemoglobin polypeptides (Fig. 4-16) as well as for certain other heme proteins, such as myoglobin.

Heme iron forms a covalent bond with histidine at F8 (sometimes referred to as the "proximal" histidine). When oxygen is bound, it forms covalent bonds with heme and the histidine at E7 (the "distal" histidine). Thus, heme is suspended in a nonpolar crevice between the E and F helices (Fig. 4-16), but, in addition, it forms Van der Waals bonds with many other parts of the molecule and in this way makes an important contribution to tertiary structure. If heme is extracted, the central helical regions, C, D, E, and F, unfold with consequent decrease in solubility.<sup>507</sup> The nonpolar environment of the heme group makes it possible for the iron to form a reversible bond with oxygen without becoming oxidized to the ferric form.

When four polypeptide chains combine to

Fig. 4-16 The tertiary structure of a single globin polypeptide chain. The helical segments labeled A through H are relatively linear; bending of the chains occurs between helices. Heme is suspended in a crevice between the E and F helices. (Courtesy of C. A. Finch.)

form the complete hemoglobin molecule, each chain lies approximately at the vertices of a regular tetrahedron. A spherical molecule, about 6.0 nm in diameter, is formed. With high resolution x-ray diffraction, the nature of the contacts between chains has been explored in detail for horse hemoglobin.<sup>519</sup> Contacts between like chains, i.e.,  $\alpha_1\alpha_2$  and  $\beta_1\beta_2$ , are limited and of little importance. The two major contacts between unlike chains have been named  $\alpha_1\beta_1$  and  $\alpha_1\beta_2$ , respectively (Fig. 4-17). (The  $\alpha_2\beta_2$  contact is the same as  $\alpha_1\beta_1$ .) The  $\alpha_1\beta_1$  contact point is extensive and moves relatively little (less than 0.1 nm) when hemoglobin is oxygenated. The  $\alpha_1\beta_2$  contact is smaller and smoother, and movement on oxygenation is relatively great (as much as 0.7 nm). As a result, there are two quaternary structures for hemoglobin: one for the deoxygenated form and one for the liganded or oxygenated form. The main difference between the two is the nature of the  $\alpha_1\beta_2$  contact (Fig. 4-17).

#### Changes in Hemoglobin Structure on Oxygenation

In the deoxy state, the oxygen affinity of hemoglobin is less than that of isolated heme subunits or that of partially oxygenated

hemoglobin. The change in oxygen affinity on oxygenation is called heme-heme (or subunit) interaction and accounts for the characteristic sigmoidal shape of the hemoglobin-oxygen dissociation curve (page 107). An additional effect of oxygenation of hemoglobin is the release of protons (the alkaline Bohr effect). These changes, as well as the interaction with 2,3 DPG (page 107), have been explained on a molecular basis in a model proposed by Perutz.<sup>518</sup>

The quaternary structure of the deoxy (low oxygen affinity) form of hemoglobin is stabilized by salt bridges involving the carboxyterminal ends of the polypeptide chains. The  $\alpha$ -terminal arginine forms two salt bridges with the adjacent  $\alpha$ -chain, one with  $\alpha 1$  (NA1) valine, and another with  $\alpha 126$  (H9) aspartate. The  $\beta$ -terminal histidine forms a salt bridge with an adjacent  $\alpha$ -chain ( $\alpha 40$  (C5) lysine) as well as an "internal" salt bridge with its own  $\beta 94$  (FG1) aspartate. An additional factor stabilizing the deoxy form is 2,3 DPG (page 102), which joins the N-terminal end of one  $\beta$ -chain to the 143 (H21) histidine of the other.

The tertiary structure of deoxygenated subunits differs slightly from that of the oxygenated form. In the deoxy form, heme iron is in a high-spin state and in this form is displaced slightly from the plane of the porphyrin ring. The penultimate tyrosine is wedged firmly between the F and H helices. When oxygen is added, iron changes to a low-spin state and moves to a position in plane with the porphyrin ring, a distance of about 0.2 nm, pulling with it the F helix to which it is attached. This movement narrows the space between the F and H helices, expelling the penultimate tyrosine from its pocket. The C-terminal amino acid is carried with the tyrosine, thereby breaking the salt bridges with adjacent chains.

The sequence of molecular changes on oxygenation is as follows: the first oxygen molecule is added, probably to an  $\alpha$ -chain, with consequent displacement of the F helix, extrusion of the penultimate tyrosine, and rupture of salt bridges. Oxygen is then added to the second  $\alpha$ -chain and to the two  $\beta$ -chains

Fig. 4-17. Quaternary structure of hemoglobin. At the left is shown the most extensive contact,  $\alpha_1\beta_1$ , in which 16 amino acids in the  $\alpha$ -chain form bonds with 18 amino acids in the  $\beta$ -chain. The  $\alpha_1\beta_1$  contact does not change significantly on oxygenation. The smaller  $\alpha_1\beta_2$  contact, shown in the center and at the right, has two forms, depending on whether the hemoglobin is in the oxygenated (oxy) or deoxygenated (deoxy) form. At  $\alpha_1\beta_2$ , 10 or 11 amino acids in the  $\alpha$ -chain form bonds with nine in the  $\beta$ -chain. Plain lines indicate Van der Waals bonds and broken lines indicate hydrogen bonds. The numbers on the lines give the number of atoms in contact (From Perutz et al.,<sup>11a</sup> courtesy of the authors and Nature.)

in sequence. With each addition, the tertiary changes in each subunit occur and salt bridges are broken. At some point, probably after the second or third oxygen is added, the quaternary structure clicks to the liganded configuration, accompanied by the expulsion of 2,3 DPG and disruption of salt bridges at the  $\alpha_1\beta_2$  contact point. Oxygen affinity is now much increased and oxygen is added to the remaining  $\beta$ -chain or chains.

The alkaline Bohr effect is explained by rupture of the salt bridges involving the  $\beta$ -C-terminal histidine and the  $\alpha$ -N-terminal valine. When these bridges are broken, the  $pK$  of the dissociation of hydrogen ion is reduced. It has also been suggested that about 25% of the alkaline Bohr effect might be accounted for by histidine at  $\alpha 122$ .<sup>522</sup>

### Globin Biosynthesis and Its Genetic Control

Synthesis of globin is accomplished by the cellular protein-synthesizing mechanisms outlined in Chapter 2 (page 47). At least four pairs of structural genes are required, one for each of the four normal polypeptide chains. In addition, there is evidence that both the  $\alpha$  and  $\gamma$  structural loci are reduplicated (page 797). The hemoglobin structural genes are carried on two pairs of autosomes. The  $\alpha$ -chain structural genes occupy loci on one pair of autosomes, and the  $\beta$ -,  $\gamma$ -, and  $\delta$ -chain structural genes occupy loci close to one another on a second pair of autosomes (page 797). A "point mutation" in one of these structural genes leads to the production of an abnormal hemoglobin characterized by the substitution of a single amino acid for another. Such abnormal hemoglobins are discussed further in Chapter 24.

In addition to the structural genes, regulator genes that control the rates of synthesis of various polypeptides are thought to exist.<sup>510,513,525</sup> Such genes may account for the changes from  $\epsilon$ - to  $\gamma$ - and from  $\gamma$ - to  $\beta$ -chain production as the fetus and infant mature. Theoretically, a mutation at one of these controller gene loci can result in

changes in the rate of synthesis of a polypeptide chain without any alteration in its structure. Such a mutation might lead to thalassemia or to the hereditary persistence of hemoglobin F (Chapter 26).

### Synchronization of Heme and Globin Synthesis

Within the erythrocyte precursor cell, heme and globin are made in nearly equivalent amounts. If heme biosynthesis is restricted, eg, in iron deficiency, a comparable reduction in globin synthesis occurs.<sup>512</sup> Furthermore, addition of heme to iron-deficient reticulocyte preparations stimulates globin synthesis.<sup>503</sup> This synchrony between the rates of globin and heme synthesis appears to be accomplished by an effect of heme on globin synthesis at the translational level.<sup>520</sup> In the absence of heme, the polyribosomes disaggregate and globin synthesis ceases. The disaggregation is reversible, and, if heme is added, the ribosomes again form into polyribosomes and globin synthesis begins. It is likely that heme acts at the initiation stage of polypeptide chain synthesis. Both positive and negative effects of heme have been observed. A repressor of chain initiation that is inactivated by heme has been described.<sup>520</sup> In addition, a factor promoting chain initiation may be activated by combining with heme.<sup>511</sup>

### Evolution of Hemoglobin<sup>502,514</sup>

The relatively complicated, tetrameric, and chemically highly organized nature of the hemoglobin molecule and the evidence for genetic control of its primary sequence have led to the development of a phylogenetic theory of hemoglobin structure. The primary structures of the  $\alpha$ - and  $\beta$ -chains are very similar. Fifty-nine of the amino acids are identical in the two chains in the order presented in Table 4-7. With only minor shifting of gaps to maximize homology, 64 amino acids may be considered identical.<sup>502</sup> Still greater homology occurs between the  $\beta$ -,  $\gamma$ -, and  $\delta$ -chains. It is postulated that the hemoglobin molecule originally was much simpler

than at present, initially consisting of a single peptide chain, probably very similar to myoglobin. To explain the appearance of new peptide chains it has been proposed that a gene duplication took place, each gene corresponding to one of the two peptide chains, which were originally identical. From this time on, the genetic material developed independently and underwent different mutations. By gene duplication,  $\gamma$ -,  $\beta$ -, and  $\delta$ -chains were produced. Dimers and tetramers of the peptide chains, such as  $\alpha\beta$  and  $\alpha_2\beta_2$ , were formed. The appearance of subunit interaction brought with it a marked increase in the physiologic effectiveness of the molecule. Such, it is postulated, are the non-lethal mutations in the hemoglobin molecule that have taken place in the past 500,000 years. On the basis of an analysis of discontinuities ("sequence gaps") in the homologous architecture of the peptide chains, attempts have been made to postulate the constitution of the original hemoglobin molecule. Braunitzer believes that the peptide chain of the hemoglobin ancestor was longer than the present  $\alpha$ - and  $\beta$ -chains. There also is reason to expect that a phylogeny based solely on molecular data derived from the study of the hemoglobins of various animal species can ultimately be developed.<sup>505</sup>

## Control of Erythropoiesis<sup>505</sup>

It is evident that a well-balanced mechanism exists that maintains the erythron within "normal" limits and mediates the response to a variety of normal and abnormal situations. In broad outlines, this control system operates in the following manner. Alterations in the concentration of hemoglobin in the blood lead to changes in tissue oxygen tension within the kidney. In response to hypoxia, the kidney secretes a factor that interacts with a plasma substrate to produce a hormone, erythropoietin. This hormone induces primitive marrow cells to differentiate into pronormoblasts, thereby bringing about expansion of the erythroid marrow and an increase in red cell production. This, in turn, leads to an increase in the size of the

erythron and an increase in tissue oxygen levels. Each of the major steps in this process will be discussed in greater detail in the sections to follow.

## Tissue Oxygen

Tissue oxygen tension depends on the relative rates of oxygen supply and demand. Oxygen supply is a complex function of interacting, but semi-independent variables, including (1) blood flow, (2) blood hemoglobin concentration, (3) hemoglobin oxygen saturation, and (4) hemoglobin oxygen affinity. Each of these functions may be altered to compensate for a deficiency in one of the others. For example, in severe anemia, cardiac output and respiratory rate may increase (page 534) and hemoglobin oxygen affinity may be reduced through the 2,3 DPG effect (page 107). Conversely, in respiratory insufficiency, secondary polycythemia occurs.

Despite the influence of cardiovascular and respiratory adjustments, tissue oxygen tension decreases roughly in proportion to the degree of anemia.<sup>560,632</sup> Conversely, induced polycythemia of moderate degree leads to normal or increased tissue oxygen tension and to increased tolerance to hypoxia.<sup>614,632,636</sup> These changes occur despite the increase in blood viscosity that accompanies polycythemia (page 124), suggesting that peripheral vascular resistance decreases to compensate for increased viscosity. However, with advanced degrees of polycythemia, the increase in viscosity may be great enough to negate the advantages of increased oxygen-carrying capacity.

That tissue hypoxia is the fundamental stimulus to erythropoiesis was first suggested by Miescher in 1893.<sup>613</sup> This concept has been amply confirmed.<sup>566,587</sup> However, it now seems clear that hypoxia does not exert its effects by a direct action on the marrow,<sup>612,631</sup> as Miescher believed, but, instead, acts by inducing the elaboration of a hormone, erythropoietin. The nature of the tissue oxygen receptors remains unknown; however, these receptors probably are located within the kidney since production of eryth-

ropoietin can be induced by renal artery constriction<sup>577</sup> or by hypoxic perfusion of the isolated kidney.<sup>576</sup>

**Erythropoietin<sup>560,575,583,584,587,591,595</sup>  
(Erythropoiesis Stimulating  
Factor, ESF)**

In 1906, Carnot and Déflandre proposed that the circulating blood carries an erythropoietic stimulating substance, "hémopoétine."<sup>559</sup> Their work was ignored, in part because they provided scanty experimental data to support their view. The report in 1950 that normoblastic hyperplasia of the bone marrow developed in both partners of parabiotic pairs of rats, only one of which was subjected to hypoxia,<sup>620</sup> renewed interest in the possibility that the hypoxic stimulus is mediated through a hormone-like factor in the blood. This possibility found additional support when a generalized increase in erythropoiesis was observed in a patient with localized hypoxia due to an A-V fistula.<sup>631</sup> Subsequently it was shown that nursing mice, kept at low oxygen tension except when suckling their young, secrete in the milk a substance that causes polycythemia in the nurslings<sup>587</sup>; furthermore, when larger amounts of plasma from anemic animals than were used in Carnot's studies were injected intravenously into normal recipients, a more impressive reticulocytosis occurred than had been observed before, and the quantity of circulating hemoglobin increased as well.<sup>566,583</sup>

It is now generally accepted that these observations can be accounted for by the effects of a hormone, erythropoietin, the production of which is related to tissue oxygen tension.

**Chemical Properties and Bioassay**

Highly purified erythropoietin has been prepared from the plasma of sheep made anemic with phenylhydrazine.<sup>581</sup> The specific activity of this preparation was 8250 units per mg of protein, indicating a more than million-fold purification, and the only contaminant

appeared to be erythropoietin lacking its sialic acid moiety. A similar degree of purity (8300 units/mg) was achieved in material prepared from the urine of anemic human subjects with hookworm disease.<sup>572</sup>

Erythropoietin is relatively stable to heat and storage. It is a glycoprotein containing sialic acid, hexoseamine, and hexoses. If the sialic acid is removed, the erythropoietic activity is lost *in vivo*,<sup>625</sup> but is retained *in vitro*. Estimates of molecular weight have ranged from 27,000 to 100,000.<sup>575,584</sup> With highly purified sheep plasma erythropoietin, molecular weight was reported to be 45,800, of which 30% was carbohydrate.<sup>581</sup> Erythropoietin migrates as an  $\alpha$ -globulin during electrophoresis.

Erythropoietin usually is detected and quantitated by means of bioassay. The most sensitive and economical assays employ ex-hypoxic, polycythemic (erythropoietically depressed) mice as the test animal and the incorporation of <sup>59</sup>Fe into circulating erythrocytes as the index of erythropoietic activity.<sup>575,584</sup> Immunologic assays, including a hemagglutination-inhibition technique and a radioimmunoassay,<sup>579</sup> appear promising but are still in various stages of development. Erythropoietin activity is expressed in units, and 1 unit is defined as that amount of activity in 1.48 mg of the first international reference preparation (IRP) of erythropoietin, formally called Erythropoietin Standard B,<sup>562</sup> or in 0.5 mg of the second IRP.<sup>555</sup> These units are approximately equivalent to the older cobalt unit, which was defined as the erythropoietic activity produced by the administration of 5  $\mu$ moles of cobalt chloride. The IRP's were prepared from pooled urine of anemic human subjects and standardized by bioassay in a number of independent laboratories. They are made available by the National Institute for Medical Research, London, England.

**Secretion**

The major site of erythropoietin production is the kidney.<sup>583,590,626,630</sup> In the dog the kidney is the exclusive source of the hor-

none.<sup>584,610</sup> In most other species, including man, removal of the kidneys does not abolish erythropoiesis nor bring about the complete disappearance of erythropoietin activity from plasma.<sup>570,580,584,607,608</sup> Furthermore, hypoxia stimulates the production of erythropoietin in renoprival subjects. Thus, in these species there are non-renal, erythropoietin-producing tissues. The liver appears to be one such tissue,<sup>580</sup> but there may be others. It has not been established that the renal and extrarenal hormones are chemically identical.

It has been difficult to extract erythropoietin from normal kidneys. However, Gordon and associates have shown that incubation of renal extracts with normal plasma leads to production of an erythropoietically active substance.<sup>561,584,585,637</sup> On the basis of their observations, they proposed that the kidney makes an enzyme called *erythrogenin* (renal erythropoietic factor, REF) that is erythropoietically inactive by itself but that reacts with a plasma substrate, *erythropoietinogen*, of hepatic origin to produce active erythropoietin. These studies have been confirmed in some,<sup>599,639</sup> but not all,<sup>569</sup> laboratories. An alternative proposal holds that erythropoietin is present in the kidney, but that its activity is inhibited, possibly by a lipid substance.<sup>573</sup> According to this proposal, plasma incubation acts by destroying or removing the inhibitor. However, the renal secretion of erythropoietin in response to a hypoxic stimulus requires DNA-dependent RNA production and the de novo, ribosomal synthesis of protein.<sup>627</sup> Therefore, it cannot be accounted for by release of preformed, inhibited hormone.

The location of the erythropoietin-secreting mechanism within the renal parenchyma remains controversial. One body of information supports the juxtaglomerular apparatus (JGA) as the secretory organ. In some experimental situations associated with increased erythropoiesis, hyperplasia and increased granularity of the JGA have been observed. Furthermore, erythropoietin release has been associated with discharge of granules from the JGA,<sup>564</sup> and a patient has been described with polycythemia and in-

creased erythropoietin production with histologically proved JGA hypertrophy (Bartter's syndrome).<sup>593</sup> However, many of these observations may relate to the known role of the JGA in renin secretion rather than erythropoietin production.<sup>584</sup> In studies employing the fluorescent antibody-staining technique, erythropoietin was found to be localized in the epithelial cells of the glomerulus, and no staining of the JGA was observed.<sup>578</sup> It was suggested that the glomerulus is the site at which *erythrogenin* reacts with its substrate. Additional support for a glomerular site of erythropoietin synthesis is the observation that tissue cultures derived from isolated goat kidney glomeruli produced erythropoietin over periods of seven months.<sup>557</sup>

Unlike erythropoietin, erythrogenin appears to be formed diffusely throughout the kidney.<sup>584,629</sup> Medullary, cortical, and isolated glomerular or tubular fractions all are active. In subcellular preparations, erythrogenin activity was found in "light mitochondrial" and "microsomal" fractions. On the basis of the time course of hypoxia-induced changes in these fractions, it was proposed that erythrogenin is secreted in the endoplasmic reticulum of microsomes and stored in the peroxisomes of the "light mitochondrial" fraction.<sup>558</sup>

## Action

The primary site of action of erythropoietin appears to be an unidentified stem cell (the "erythropoietin sensitive cell,"<sup>584</sup> page 51). This cell is conceived to be committed to the erythrocyte cell line and a precursor to the pronormoblast. Addition of erythropoietin to *in vitro* cultures of rat bone marrow leads to an increase in iron uptake and the synthesis of a species of RNA with a sedimentation coefficient of 9s.<sup>592</sup> Presumably, the latter is the messenger for globin synthesis. Thus, erythropoietin appears to activate controller and structural genes essential to hemoglobin synthesis, and in so doing causes the erythropoietin-sensitive cell to assume the morphologic features of a pronormoblast. In addition, there is evidence

that self-replication and proliferation of the erythropoietin-sensitive cells are stimulated by erythropoietin.<sup>621</sup> Ultimately, these effects lead to expansion of the marrow erythrocyte production compartment (erythroid hyperplasia).<sup>615</sup>

Erythropoietin also may have other actions.<sup>584, 615</sup> Red cell generation time is shortened, cellular divisions may be skipped,<sup>628</sup> premature denucleation occurs, and reticulocytes are released to the blood at an earlier stage of maturity.<sup>615, 618</sup> These mechanisms result in the release of a population of erythrocytes that are macrocytic, hypochromic, and polychromatophilic and have a relatively short life span. Obviously, such a population has only limited utility and can contribute to improved function for only a short time.

#### Erythropoietin Levels in Health and Disease

Erythropoietin can be detected in both urine and plasma. In various laboratories employing the polycythemic mouse assay, normal values for urine erythropoietin in men have been reported to be 1 unit/day,<sup>634</sup>  $2.8 \pm 1.3$  units/day (mean  $\pm$  1 SD),<sup>552</sup> or  $4.2 \pm 1.3$  units/day.<sup>549</sup> Values in women were about 50% lower. It seems likely that the rate of urinary excretion bears a relation to the rate of production of the hormone. However, the amount in the urine constitutes less than 10% of the amount produced, and little is known regarding the fate of the remainder.<sup>554</sup>

With the mouse assay, erythropoietin has also been detected in normal plasma,<sup>606</sup> but the level cannot be measured with accuracy until it reaches about three times normal. With an immunologic assay, normal values of 7.5 to 60 mU per ml of plasma were reported.<sup>597</sup>

The occurrence of erythropoietin in the urine and plasma of normal persons constitutes evidence that the hormone is required for normal erythropoiesis. Additional support for this belief comes from the observations

that administration of antibodies to erythropoietin depresses normal erythropoiesis,<sup>598, 624</sup> and that hypertransfusion of normal subjects decreases urinary erythropoietin levels.<sup>549</sup>

When anemia is induced in normal persons by phlebotomy, urinary erythropoietin levels increase, and an inverse relationship between the VPRC and the logarithm of urinary erythropoietin can be demonstrated<sup>549</sup> (Fig. 4-18). A similar relation probably exists in a variety of situations in which an intact erythropoietin-secreting system is associated with anemia, including iron-deficiency anemia, pernicious anemia, leukemia, aplastic anemia, sickle cell anemia, and others.<sup>609, 634, 635</sup> There are, however, several conditions in which the erythropoietin level in urine or plasma is lower than would be predicted by the curve in Figure 4-18. These include the anemias of renal insufficiency,<sup>551</sup> chronic disorders (cancer, infection, and rheumatoid arthritis)<sup>633</sup> (Chapter 18), protein-calorie malnutrition (page 136), certain endocrine deficiency states (Chapter 19), and the anemia associated with abnormal hemoglobins with reduced oxygen affinity, such as hemoglobin Seattle (page 815). The low levels in these disorders suggest that either reduced erythropoietin secretion is a factor in the pathogenesis of the anemia or tissue oxygen delivery is appropriate to body needs despite reduced hemoglobin concentration.

Erythropoietin levels also have been studied in conditions associated with polycythemia. A prompt increase in plasma erythropoietin occurs in individuals subjected to acute hypoxemia,<sup>549, 573</sup> and increased values are found in permanent residents of high altitudes.<sup>631</sup> In patients with polycythemia secondary to hypoxia, erythropoietin levels are usually increased, sometimes greatly so, but if the polycythemia adequately compensates for the hypoxia, erythropoietin may return to normal limits.<sup>549</sup> On the other hand, in polycythemia vera, erythropoietin levels are uniformly low, and red cell production in this illness appears to be independent of the usual control system.<sup>549</sup> Finally, a number of instances of polycythemia associated

Fig 4-18. Relation of the volume of packed red cells (hematocrit) to urine erythropoietin (log scale) in normal individuals subjected to phlebotomy. The same relationship probably holds for many common anemias in which the erythropoietin secreting mechanism is intact. If points fall significantly below the line, this suggests that defective erythropoietin secretion may be important in the pathogenesis of the anemia. (From Adamson,<sup>549</sup> courtesy of the author and Henry M. Stratton, Inc.)

with tumors, especially hypernephromas, cerebellar hemangioblastomas, and hepatomas, have been reported (page 986). In some of these, erythropoietin-like materials were found in urine or plasma or in extracts of the tumor, suggesting that this association represents unregulated secretion of erythropoietin by neoplastic tissue.<sup>549</sup>

### Role of the Nervous System

Regulation of erythropoiesis by the nervous system has long been postulated, but the evidence has been unconvincing.<sup>557</sup> More recently, electrical stimulation of brain areas in or near the hypothalamus has induced reticulocytosis, increases in the red cell mass, and increases in erythropoietin production.<sup>574,558,601</sup> Also, the induction of large,

hypothalamic lesions has inhibited the erythropoietic response to hypoxia.<sup>589,604</sup> Finally, atropine has been shown to prevent the reticulocytosis of hypothalamic stimulation as well as the erythropoietin response to hypoxia.<sup>575</sup>

The physiologic importance of these observations remains to be established. It is possible that the hypothalamus senses tissue oxygen levels and stimulates erythropoiesis, either through a neurohypophyseal humoral mechanism or via the sympathetic nervous system. Alternatively, the observed effects may result from unphysiologic variations in vascular dynamics or blood oxygenation.<sup>544</sup> Since the deoxygenated human renal homograft can resume erythropoietin production,<sup>563</sup> it is unlikely that this function is mediated by nerve fibers.

### Other Erythropoietic Substances

The importance of *androgens* in erythropoiesis has long been inferred from the observed differences between adult men and women in the measures of red cell concentration. Values for the volume of packed red cells, blood hemoglobin concentration, and red cell count in males exceed those in females, the differences becoming apparent at puberty (see Appendix, Table A-1). Castration in adult males is followed by a reduction in the above measures to levels typical of females. Furthermore, administration of physiologic doses of androgens to patients with hypogonadism or panhypopituitarism leads to an increase in the volume of packed red cells.<sup>563,592,593</sup> Finally, in pharmacologic doses, androgens may bring about improvement in certain, otherwise refractory anemias, such as aplastic anemia (Chapter 56), myelofibrosis (Chapter 57), or sideroblastic anemia (Chapter 18).

There appear to be several mechanisms whereby androgens exert their effects. There is little doubt that they stimulate erythropoietin production.<sup>553,599,622</sup> This effect may be partially explained by the induction of renal hypertrophy,<sup>600,601</sup> but there is an additional, more rapid action since increased erythropoietin secretion can be demonstrated in isolated kidneys perfused with androgens.<sup>599</sup> Androgens may also potentiate the action of erythropoietin, perhaps by increasing the number of erythropoietin-sensitive stem cells.<sup>602,611</sup> Finally, there are studies suggesting that androgens exert a direct effect on erythropoiesis without the intermediation of the erythropoietin system.<sup>567,589,619</sup>

*Estrogens* may exert an inhibitory effect on red cell production. Castration in female rats causes an increase in the red cell count, and administration of estradiol is followed by a drop in the elevated counts. In small doses, estrogens may decrease the stem cell response to erythropoietin.<sup>592</sup> In very large doses, they may suppress erythropoietin production.<sup>605</sup>

A mild to moderate anemia is observed with deficiency of *thyroid hormone* in myxedema or following thyroidectomy or pro-

longed administration of antithyroid drugs (Chapter 19). The anemia may be corrected by administration of thyroid hormone. It is likely that thyroid hormone exerts its effects on erythropoiesis indirectly, by altering the tissue demand for oxygen. Similarly, *cortisol*<sup>592</sup> and *growth hormone*<sup>623</sup> probably also affect erythropoiesis secondarily by a similar mechanism. Evidence for the oxygen demand hypothesis is considered in Chapter 19 (page 711).

Certain other hormones may affect red cell production. *Placental lactogen*<sup>592</sup> and *prolactin*<sup>592</sup> appear to stimulate erythropoiesis directly, but erythropoietin must be present for maximum effect. A number of *vasoactive hormones* stimulate erythropoiesis, probably by decreasing blood flow to the renal hypoxia-sensing mechanism, thereby inducing erythropoietin secretion.<sup>575</sup> These vasoactive materials include vasopressin, angiotensin, 5-hydroxytryptamine, norepinephrine, and prostaglandin E.

The *carotid body* has been implicated as a source of an erythropoietic hormone in cats.<sup>633</sup> Other investigators, however, found, instead, that the erythropoietic response of cats to hypoxia was enhanced by carotid body removal.<sup>617</sup> Furthermore, no evidence of impaired erythropoiesis could be detected in 57 human subjects who had had both carotid bodies removed.<sup>598</sup>

*Cyclic adenosine monophosphate (cAMP)* has been shown to stimulate erythropoiesis in rodents.<sup>536,626</sup> Since this effect was blocked by an erythropoietin antibody, it was considered likely that cAMP acted by stimulating erythropoietin production.<sup>626</sup> In addition, however, a direct effect on the marrow was suggested by the observation that cAMP induced the activity of aminolevulinic acid synthetase (page 169) in rabbit bone marrow cultures.<sup>556</sup> There was, however, no increase in iron uptake or in overall heme synthesis in such a system.<sup>586</sup>

The injection of *hemolysates*, *hemoglobin*, or *hemin* has been shown to stimulate erythropoiesis, and this phenomenon has been offered as an explanation for the increased erythropoiesis in patients with compensated

hemolytic anemia and normal blood hemoglobin levels. The effect of these materials appears to depend on erythropoietin secretion<sup>571,613</sup> and may well represent a toxic or pharmacologic effect on the kidney rather than a physiologic mechanism.<sup>571</sup>

## *Destruction of Erythrocytes*

The Life Span of the Erythrocyte  
Erythrocyte Aging  
Mechanisms of Red Cell Destruction  
Sites of Erythrocyte Destruction  
Hemoglobin Catabolism

IN the preceding chapters the structure, chemical composition, and metabolism of the red cell were discussed, as were the substances required for hemoglobin production and the manner in which hemoglobin synthesis is accomplished. The red corpuscle is a highly specialized structure that loads, transports, and unloads oxygen with speed and efficiency and yet consumes little of this vital gas itself. Its survival depends upon its ability to maintain its unique physical properties despite the chemical variations in its environment and the continuous physical abuse to which it is subjected in the circulation. The biologic truism that, as specialization increases, adaptability and durability are more or less proportionately diminished applies to the red corpuscle. Being incapable of much repair, it is ultimately destroyed. The continuous excretion of bile pigment gives evidence of the continuity of the process of red cell breakdown.

### **The Life Span of the Erythrocyte**

Valid measurements of erythrocyte survival in the intact animal became possible in 1919 when Ashby devised the differential agglutination technique.<sup>2</sup> Since then, other, less cumbersome methods have been intro-

duced. Studies with these techniques have demonstrated that, after a finite life span, the erythrocyte becomes nonviable and disappears from the circulation. In man, this life span averages approximately 120 days. In other mammals, values range from as short as 40 days in mice to as long as 225 days in the llama.<sup>3</sup> Still longer survivals, 600 to 1400 days, are observed in poikilothermic reptiles with low metabolic rates, such as toads and turtles.<sup>1</sup>

In addition to red cell destruction associated with senescence, there is some degree of random erythrocyte breakdown. The latter is minimal in normal man, but may increase greatly under pathologic circumstances. In other species, especially the pig<sup>5</sup> and the llama,<sup>19</sup> a greater degree of random destruction than in man is observed under normal circumstances.

### **Methods for Estimating Erythrocyte Life Span**

Erythrocyte life span may be determined indirectly from ferrokinetic studies (page 164) or from measurements of the rate of heme catabolism (page 216). There are also a number of direct methods for measuring erythrocyte life span. These fall into one of two categories.<sup>3,4</sup> Cohort methods depend on the incorporation of an isotopically labeled substance into a group ("cohort") of newly formed cells. If exposure to the label is brief and if there is no reutilization of label, the tagged cells will be of very nearly the same age. In contrast, random-labeling methods utilize tracers that bind with all cells in the circulation regardless of age. The patterns of

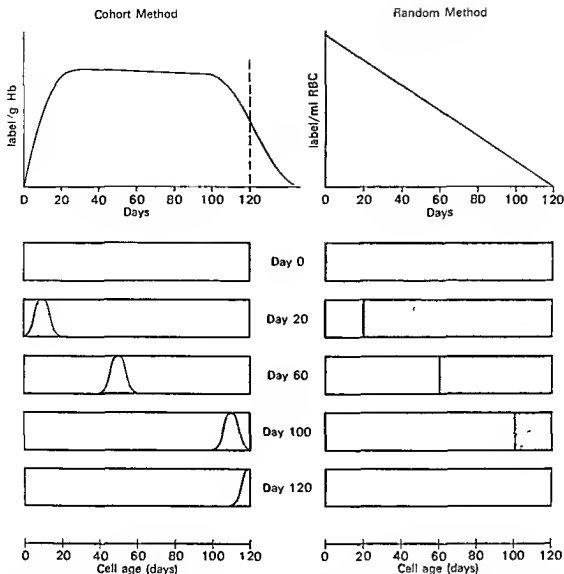

Fig. 5-1 Comparison of idealized patterns produced by cohort and random methods of labeling circulating erythrocytes. These curves are constructed on the assumption that there is no elution of label and that all erythrocyte destruction is senescent. In the bar below the main graphs the distribution of labeled cells (shaded areas) by cell age is indicated. These labeled cells can be thought of as being forced to the right by a piston made of newly produced, unlabeled cells (Modified from Berlin,<sup>4</sup> courtesy of the author and JAMA)

time-dependent change in circulating red cell label produced by these two procedures are quite different (Fig. 5-1). Cohort labels result in a curve characterized by a plateau, the length of which is a measure of erythrocyte life span. In contrast, random labels begin to disappear from the circulation immediately and erythrocyte life span is related to the time when all the label has vanished, the so-called extinction time.

### Cohort Methods

Precursors used for cohort labeling include  $^{59}\text{Fe}$ ,  $^{75}\text{Se}$ -methionine,<sup>24</sup> and glycine tagged with  $^{15}\text{N}$ ,  $^{14}\text{C}$ , or  $^3\text{H}$ . These are incorporated into hemoglobin synthesized by the erythrocyte precursors and remain with the cell throughout its life span. Another cohort-labeling method<sup>6</sup> employs a combination of non-radioactive diisopropylfluorophosphate

(DFP) and  $DF^{32}P$ . In order to determine erythrocyte life span with cohort labels, assays must be performed for 135 to 150 days if the red cell life span is normal. Of the available cohort labels,  $^{59}Fe$ ,  $^{75}Se$ -methionine, and  $DF^{32}P$  are reasonably safe and relatively easy to assay. The requirement for the use of a mass spectrometer limits the usefulness of  $^{15}N$ -glycine,  $^3H$ -glycine and  $^{14}C$ -glycine, which emit low-energy beta particles, must be assayed by liquid scintillation or low background Geiger counting. Both isotopes have dangerously long physical and biologic half-lives.

### Random-Labeling Methods

Random-labeling methods have proved to be much more useful than cohort methods for both clinical and research applications because accurate information is made available in a relatively short time. Once enough assays have been made to establish the form of the disappearance curve, it may be extrapolated to the base line to determine the extinction time. The latter is directly related to the finite (senescent) life span. More frequently, the time at which half of the label has disappeared from the circulation ( $t_{1/2}$ ) is recorded. When there is neither a significant degree of random destruction nor elution of label, the form of the disappearance curve is linear, and mean erythrocyte life span is equal to twice the value for  $t_{1/2}$ .

Random methods include those based on the Ashby differential agglutination technique as well as those in which cells are labeled with  $^{51}Cr$ ,  $^3H$ -DFP or  $DF^{32}P$ . Preliminary studies indicate that  $^{14}C$ -cyanate may also be a useful, non-eluting random label.<sup>20</sup> The Ashby method<sup>2,9</sup> requires the transfusion of compatible but immunologically identifiable blood, eg, group O cells into a group A recipient. At appropriate intervals, the donor red cells are enumerated following agglutination or hemolysis<sup>17</sup> of the recipient's cells by appropriate antisera. Methods for automating the procedure have been described.<sup>23</sup> When properly performed the differential agglutination technique yields ac-

curate results. The observed disappearance curves are linear in normal human subjects, and deviation from linearity indicates random destruction. Inability to measure the survival of a subject's cells in his own circulation as well as the hazards of transfusion and the exacting requirements of technique limit the usefulness of the method.

Radioactive chromium was introduced as a red cell label in 1950<sup>14</sup> and was utilized in survival studies in vivo shortly thereafter.<sup>10,11,22</sup> Anionic (hexavalent) chromium in the form of the chromate ion ( $^{51}CrO_4^{2-}$ ) can penetrate the red cell membrane. Once inside the cell it is converted to the trivalent cation ( $Cr^{+3}$ ) and in this form becomes firmly, but not irreversibly, bound to hemoglobin. Cationic chromium may be used to tag plasma proteins, but it will not penetrate, and therefore will not label, the erythrocyte. Because of the change to the cationic form, there is no reutilization of the chromium label. The chromium attaches to the beta chains of hemoglobin A and the gamma chains of hemoglobin F.<sup>15,23</sup>

The chromium method is probably used more than any of the other available methods. Several factors account for its popularity. Since it emits a high-energy gamma ray, radioassay is comparatively easy and requires little sample preparation. Furthermore, radioactivity can be monitored over the body surface to determine the principal sites of destruction. Since labeling can be, and usually is, performed ex vivo, cross-transfusion studies are possible; thus, survival of a patient's cells in a normal recipient or of normal cells in a patient can be evaluated. Still another advantage of the ex vivo chromium method is that red cell volume also may be determined (page 122).

The principal disadvantage of the chromium label is that it is slowly eluted from the cell. The rate of elution in normal subjects was found to be 0.57 to 1.28% per day and averaged 0.93% per day.<sup>10,11</sup> In most patients with various hematologic diseases, the chromium elution rate was 0.62 to 2.27% and averaged 1.29% per day; in a small number a second, much more rapid, elution rate

constant was observed, namely 8 to 14% per day.<sup>7</sup> An assumed rate of 1% per day is often used for analysis of chromium survival curves (see below). The disappearance of  $^{51}\text{Cr}$  from the circulation thus reflects not only the red cell life span, but also the elution rate. Another consequence of chromium elution is a nonlinear disappearance curve. However, if the data are plotted on a semilogarithmic scale, or if appropriate correction factors<sup>18</sup> are applied (Fig. 5-2), the pattern approximates a straight line. From such a plot, the disappearance half-time ( $t_{1/2}\text{Cr}$ ) may be derived.

The chromium elution rate depends in part on the technique used in the labeling procedure.<sup>21</sup> Consequently, reported average normal values for  $t_{1/2}\text{Cr}$  have varied widely, from 25 to 33 days. In order to standardize methodology, an international committee has specified a labeling procedure and, furthermore, has recommended that the use of  $t_{1/2}\text{Cr}$  as a method of expressing results be abandoned.<sup>18</sup> Instead, a mean red cell life span is to be calculated. To do so, the chromium survival data should first be corrected for elution by means of correction factors specified by the committee. Then the data should be made to fit either an arithmetic (linear) or an exponential disappearance curve by means

Fig 5-2  $^{51}\text{Cr}$  erythrocyte survival curve in a normal subject before (A) and after (B) correction for elution (see text). Half of the radioactivity is gone at 30 days ( $t_{1/2}\text{Cr}$ ) but the radioactivity does not disappear completely until 115 days, the so-called extinction time

of a least-squares fitting procedure. The "goodness of fit" is assessed. If the data best fit a linear plot, the mean red cell life span is determined from the reciprocal of the slope, eg, by multiplying the  $t_{1/2}$  by 2. If they best fit a semilogarithmic plot, the reciprocal is obtained by multiplying the  $t_{1/2}$  by 1.44. In theory, a linear disappearance curve should be found with senescent destruction and an exponential curve with random destruction. A possible objection to the recommended method of analysis is that the correction factors assume a single value for the  $^{51}\text{Cr}$  elution rate, even though variation within the normal and in disease is to be expected. For this reason, until the committee's recommendations have been fully accepted, both a  $t_{1/2}\text{Cr}$  and a mean red cell life span had best be calculated.

Diisopropylfluorophosphate labeled with  $^{32}\text{P}$  ( $\text{DF}^{32}\text{P}$ ) reacts with esterases, especially cholinesterase, and becomes firmly bound to the cell. In contrast to chromium, DFP is not eluted after the first 24 to 48 hours. As a result, the normal disappearance curve is linear and many complexities of interpretation are avoided.<sup>12,13</sup> For these reasons,  $\text{DF}^{32}\text{P}$  is probably the most satisfactory label for determining life span, although sample preparation is somewhat complicated because the usually available equipment for detecting the high-energy beta particles emitted by  $^{32}\text{P}$  requires that the samples be taken to dryness. Labeling is most effectively accomplished in vivo; a single injection of  $\text{DF}^{32}\text{P}$ , not to exceed 20  $\mu\text{g}/\text{kg}$  body weight, in propylene glycol is administered intravenously over a period of 10 to 15 minutes.<sup>6,18</sup> Ex vivo labeling is possible, but a large volume of blood (100 to 200 ml) is required<sup>16</sup> and cross-transfusion studies are therefore cumbersome. The isotope cannot be used if counting over body surfaces is desired.

### Double Labeling

Double labeling makes possible the comparison of two erythrocyte populations, eg, recipient and donor populations, in a single

host, and is one means of distinguishing intracorporeal and extracorporeal hemolytic mechanisms (page 720). Double labeling may be accomplished with the use of immunologic and isotopic methods<sup>10</sup> or with two isotopes.<sup>8,10</sup>

### Comparison of Cohort- and Random-Labeling Methods<sup>3</sup>

Some of the advantages and disadvantages of the cohort- and random-labeling procedures have been discussed in the preceding paragraphs. The random-labeling methods provide the more rapid means for determining the red cell life span, but it may be difficult to distinguish between a shortened but finite life span and random destruction

of low intensity, if this distinction is important.

It is usually desirable to perform studies of erythrocyte life span in the steady state, i.e., when erythrocyte production and destruction are equal and the circulating red cell volume remains constant over the period of study. If these conditions are not met, certain errors in interpretation are to be expected. These errors generally are greater with random-labeling methods than with the cohort-labeling techniques. For example, if it is assumed that the red cell volume is constant when, in fact, it is decreasing, then the rate of change of label per ml RBC will be factitiously low, and the red cell life span will be estimated as being longer than it really is (D in Fig. 5-3). In the extreme, if production of red cells is at a standstill, no change in

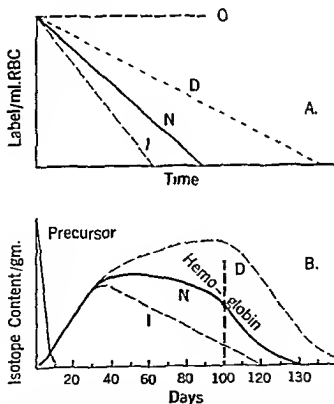

Fig 5-3. Schematic diagrams of data derived from random labeling of red cells (A) and from cohort labeling (B). N indicates the normal findings. The effect of a changing total red cell volume on the measurement of red cell life span is also shown. O indicates absence of erythropoiesis. D refers to decreasing red cell volume. I refers to increased red cell volume. (Modified from Berlin<sup>3</sup>)

label content per ml RBC would be detected and the red cell life span would appear to be infinite (O in Fig. 5-3). When the rate of production increases and the total red cell volume is increasing, the calculated red cell life span would be falsely short (I) as compared with the normal (N).

External bleeding results in an apparent shortening of red cell life span. If a random-labeling method is used and 20 ml of red cells are lost per day by any route, the red cell life span will appear to be only half normal. The only completely satisfactory solution for problems arising from changes in total circulating red cell volume during the course of life span measurements consists in determining the changes in total circulating isotope by measurement of the total red cell volume. A partial correction can be achieved by expressing the data in terms of radioactivity per ml of whole blood. A changing red cell mass also leads to factitious changes in the plateau-type curve derived from cohort labeling (Fig. 5-3, B).

The life span of the normal erythrocyte as measured by the various procedures described above is essentially the same, namely, 117 (110 to 135) days by the Ashby method, 113 (108 to 120) days when the  $^{51}\text{Cr}$  label was measured to extinction, 118 (109 to 127) days with  $^{15}\text{N}$ -glycine, and 124 days with  $\text{DF}^{32}\text{P}$ . Thus it appears that approximately 0.83% of the circulating red cells is replaced each day.

### Clinical Application of Life-Span Measurements

Findings in various pathologic states will be discussed in later chapters. In spite of their limitations, measurements of red cell life span have been found useful in the study of unexplained anemias not clarified by simpler means. The life span of red cells may be shortened as the result of some intrinsic defect such as occurs in the hemoglobinopathies and in red cell enzyme deficiencies or because of some extrinsic mechanism that causes the cell to be removed prematurely, as in the presence of hemolytic antibodies. These can

be distinguished by cross-transfusion studies utilizing a normal subject as donor and/or recipient. The type of curve of disappearance of red cells also can be of value. Thus, when the results are plotted on arithmetic graph paper, the course of elimination of red cells from the patient's circulation may be slow, uniform, and practically straight, indicating a senescent form of destruction. In contrast, in the acquired hemolytic anemias the rate of elimination is not only accelerated but it is at first rapid and then gradually slows (exponential). This indicates random destruction of red corpuscles without relation to their age.

In many instances, however, life-span measurements only confirm, and express in quantitative terms, what has been suspected already. Unfortunately, their importance has sometimes been exaggerated. Not only must technical limitations be given full consideration, but the role of multiple biologic influences must receive due attention.

## Erythrocyte Aging

Once the erythrocyte has lost its nucleus, mitochondria, and ribosomes, it no longer has the ability to synthesize proteins. During its subsequent existence, certain of the red cell enzymes gradually lose activity with a consequent deterioration of the metabolic processes dependent upon them (Table 5-1). Because such changes occur in the glycolytic pathway (Table 5-1), ATP becomes less available as the cell ages. Because ATP is the major source of energy in the red cell, energy-dependent processes become impaired, especially the transport of sodium and potassium. It is likely that loss of ATP also is responsible for the decrease in red cell deformability that occurs with aging.<sup>45,54</sup>

Failure of the pentose phosphate pathway (Table 5-1) may also be an important factor in aging of the erythrocyte. When this step fails, the cell is unable to protect itself from oxidative damage. This may result in alterations in hemoglobin structure and function (Table 5-1). Ultimately, irreversible changes in hemoglobin may occur (page 104).

## Mechanisms of Red Cell Destruction

Which of the changes listed in Table 5-1 ultimately renders the erythrocyte nonviable remains unknown. Equally mysterious are the morphologic events accompanying red cell destruction. At least five major possible mechanisms of destruction have been defined, chiefly on the basis of either *in vitro* observa-

tions or study of exaggerated modes of destruction occurring in patients with hemolytic anemia. These mechanisms are (1) fragmentation, (2) osmotic lysis, (3) erythrophagocytosis, (4) complement-induced cytolysis, and (5) hemoglobin denaturation. As yet, the relative importance of each of these mechanisms in the destruction of normal cells remains unsettled.

### Fragmentation

Fragmentation may be defined as the loss of a portion of the erythrocyte membrane, often, but not always, accompanied by loss of cellular contents, including hemoglobin.<sup>98</sup> Fragmentation has been produced *in vitro* by a variety of techniques,<sup>98</sup> including microdissection,<sup>92</sup> thermal injury,<sup>80</sup> the forcing of cells through a micropipette of 2.5  $\mu$ m diameter,<sup>86,89</sup> or by the passage of cells through either a loose fibrin clot or an "artificial clot" made of nylon or glass fibers.<sup>73</sup> After a portion of the cell is lost, the membrane appears to be capable of self repair. In the intact organism, smaller fragments are probably removed from the circulation by reticuloendothelial cells; however, larger fragments may circulate, appearing on blood smears as small, misshapen, often triangular or "helmet-shaped" structures ("schistocytes"). Fragmentation is the characteristic mode of destruction in the "traumatic" and "microangiopathic" hemolytic anemias (Chapter 28) and is also a part of the destructive process in sickle cell anemia (Chapter 25) and the Heinz body anemias (Chapter 23).

That fragmentation is the chief means of destruction of normal cells was suggested by Rous and Robertson.<sup>92</sup> These investigators could find no morphologic signs of disintegrating, whole red cells (erythrophagocytosis) in the course of an organ-by-organ search of the body. They therefore concluded that, when the cell is deformed by passage through the microcirculation, portions are broken off until finally a fine, hemoglobin-containing dust is formed that is removed by the macrophages of the reticuloendothelial system. Some support for their hypothesis is found

Table 5-1. Changes in the Erythrocyte with Aging

- 1 Changes in glycolysis
  - a Enzyme activities which decrease
    - hexokinase<sup>34 36 37</sup>
    - phosphoglucose isomerase<sup>47</sup>
    - phosphofructokinase<sup>41</sup>
    - aldolase<sup>37</sup>
    - glyceraldehyde-3-phosphate dehydrogenase<sup>44</sup>
    - pyruvate kinase<sup>38 41</sup>
  - b Overall rate of glycolysis decreases<sup>33 38</sup>
  - c Phosphorylated intermediates which decrease
    - ATP<sup>37,44</sup>
    - 2,3 DPG<sup>33,42</sup>
- 2 Changes in the pentose phosphate pathways
  - a Glucose-6-phosphate dehydrogenase decreases<sup>34 35,37 47</sup>
  - b 6-Phosphogluconate dehydrogenase decreases<sup>35,37 47</sup>
- 3 Changes in the membrane
  - a Lipid content decreases<sup>52 55 56</sup>
  - b Surface area decreases<sup>52</sup>
  - c Negative charge decreases<sup>53</sup>
  - d Cellular cation content is altered K<sup>+</sup> decreases, Na<sup>+</sup> increases<sup>33,50</sup>
- 4 Activity of miscellaneous enzymes which decreases
  - Glutamate-oxaloacetate transaminase<sup>32 34 38 51</sup>
  - Cholinesterase<sup>32</sup>
  - Catalase<sup>31</sup>
  - Glyoxylase<sup>31</sup>
  - Isocitrate dehydrogenase<sup>34</sup>
  - Transketolase<sup>35</sup>
- 5 Changes in hemoglobin
  - a Increased methemoglobin<sup>44</sup>
  - b Increased hemoglobin A<sub>2</sub><sup>48</sup>
  - c Increased oxygen affinity<sup>40 42</sup>
- 6 Changes in physical properties
  - a Increased density<sup>39 49</sup>
  - b Decreased deformability<sup>45</sup>
  - c Increased osmotic and mechanical fragility<sup>43 47</sup>
- 7 Decreased cell size<sup>43 57</sup>

in the observation that the membrane becomes less and less deformable as the erythrocyte ages,<sup>45</sup> possibly because of depletion of ATP.<sup>54</sup> Such cells are more easily fragmented when deformed. In addition, the observation that the mean corpuscular volume and mean corpuscular hemoglobin decrease as the cell ages can only be explained by loss of a portion of the cell without total destruction.<sup>77</sup>

### Osmotic Lysis

Because of the osmotic effect of hemoglobin, erythrocytes tend to gain water; however, under normal circumstances this tendency is countered by an energy-dependent mechanism that pumps sodium and water out of the cell (page 100). If the rate of water entry exceeds the capacity of the pump, or if the operation of the pump is impaired, the cell gains water. Then the erythrocyte swells and changes in shape from a biconcave disc to a sphere. Normal erythrocytes can swell to as much as one and one half or two times their original volume without loss of contents.<sup>82, 96</sup> Further swelling, however, leads to the development of transient defects in the membrane, as great as 20 to 50 nm in diameter, through which hemoglobin and other macromolecules may pass.<sup>90</sup> This sequence of events is usually called osmotic or colloid-osmotic lysis; however, the term "lysis" is inexact since the membrane alteration is reversible, and cells that have undergone osmotic hemolysis can regain their osmotic integrity.

Osmotic lysis may be induced in vitro by exposure of cells to hypotonic saline solutions (the osmotic fragility test, page 734). Also, maneuvers that impair the function of the sodium pump may induce osmotic lysis.<sup>81</sup> Such maneuvers include inhibition of glycolysis—the source of the ATP that powers the pump—either by prolonged incubation in the absence of glucose or with chemical inhibitors such as fluoride. Similar effects can be obtained with agents acting on membrane ATPase, such as ouabain.

Increased membrane permeability (leakiness) is a consequence of certain kinds of red

cell damage<sup>84</sup> including the genetic abnormality of hereditary spherocytosis and some types of antibody damage (Chapter 27). Cells thus damaged may survive if they can compensate for their defect by increasing the rate of outward transport of sodium and water. However, if deprived of energy substrates, as may occur in the spleen, compensation fails and osmotic lysis ensues.

Spherical cells (spherocytes) are especially susceptible to osmotic lysis; therefore, this form of erythrocyte destruction is characteristic of hemolytic diseases accompanied by spherocytosis (Chapters 20, 21 and 27). Also, hereditary disorders of glycolytic enzymes may lead to failure of active transport and osmotic hemolysis. The importance of osmotic lysis in destruction of normal cells is unclear; however, depletion of glycolytic enzymes and increased osmotic fragility are characteristic changes in aged erythrocytes (Table 5-1).

### Erythrophagocytosis

Erythrophagocytosis refers to the ingestion of whole red cells by circulating monocytes or neutrophils or by fixed macrophages of the reticuloendothelial system. The phenomenon was probably first observed by Ehrlich, who placed a ligature around the finger of a patient with paroxysmal cold hemoglobinuria (page 915), chilled the finger, and collected blood from the fingertip.<sup>76</sup> Macrophages containing whole red cells were observed on microscopic examination.

When blood from normal subjects is incubated for one hour at 37° C, few of the phagocytic cells contained therein (less than 3/100,000) ingest red cells. In contrast, erythrophagocytosis is common in similarly treated blood from most patients with acquired hemolytic anemia.<sup>99</sup> The phenomenon appears to require that viable phagocytes be exposed to damaged erythrocytes,<sup>93, 97</sup> especially erythrocytes coated with complement-fixing antibodies.<sup>72, 78, 79</sup> Physiologic conditions of pH, temperature, and serum osmolality are required for optimal activity.

The process is blocked by metabolic inhibitors, especially iodoacetate, fluoride, dinitrophenol, and, to a lesser extent, cyanide.<sup>79</sup>

Erythrophagocytosis has been observed *in vivo*, especially in immunologic hemolytic anemias, but also in certain other forms of red cell injury.<sup>99</sup> Experimental induction of *in vivo* erythrophagocytosis has been accomplished by injection of antibodies directed against the red cell<sup>72</sup> or by damaging red cells in certain other ways.<sup>85,87</sup>

Erythrophagocytosis appears to be chiefly a pathologic phenomenon. Although it is often assumed to be an important mechanism for the disposal of normal, senescent red cells,<sup>90</sup> there is little direct evidence for this assumption. In one *in vitro* system employing allogeneic (mouse) macrophages, "old" human cells were phagocytized, but fresh ones were not<sup>97</sup>; however, the relation of this observation to the normal *in vivo* situation is uncertain. If all of the 200 billion normal red cells that are destroyed each day underwent erythrophagocytosis, one would expect to find morphologic evidence in careful examination of the RE system at autopsy.<sup>92</sup>

### Complement-Induced Cytolysis

One of the properties of complement (page 333) is the ability to attach to cells and induce lysis. The usual event that triggers cellular fixation of complement is the reaction between a cellular antigen and a humoral, "complement-fixing" antibody. In addition, complement is important in certain kinds of cell lysis apparently unrelated to antigen-antibody reactions, such as that which characterizes erythrocytes from patients with paroxysmal nocturnal hemoglobinuria (PNH) (Chapter 29).

The C8 and C9 components of complement appear to be the lytic agents. Although the exact nature of their interaction with the erythrocyte membrane is not known, the end result is the formation of pore-like defects in the membrane. Subsequent cell destruction proceeds by one of two mechanisms: (1) having become excessively permeable to water

and electrolytes, the cell undergoes osmotic lysis; or (2) hemoglobin and other constituents leak out of the cell directly without an intervening stage of osmotic swelling. *In vitro* models of the two mechanisms have been studied.<sup>94,95</sup> Lysis of the osmotic variety was produced by reacting human erythrocytes with complement and heteroimmune (rabbit) anti-erythrocyte serum.<sup>93</sup> Lysis in this system could be blocked by adding dextran of about 20,000 molecular weight to the medium. In contrast, anti-A antibodies induced non-osmotic hemolysis, and this could not be blocked with dextran. Lysis of erythrocytes from PNH was also of the latter type.<sup>94</sup> The explanation for the two modes of destruction remains controversial. In the view of one group of investigators,<sup>94,95</sup> the size of the membrane defects is the important factor. If they are smaller than 3.25 nm—the effective diffusion radius of hemoglobin—osmotic lysis ensues. If they are larger than 3.25 nm, hemoglobin can leak out without osmotic swelling. The effect of dextran, the molecular radius of which is about 3.2 nm, is explained by its action in countering the colloid osmotic pressure of hemoglobin. The factors controlling hole size are not completely understood, but appear to be a function of the nature or distribution of the antigen. Factors relating to the complement or the antibody are of little importance.

Another group of workers believes that it is the number of defects, rather than their size, that affects the type of hemolysis.<sup>75</sup> With the electron microscope, by means of a negative staining technique, this group demonstrated the complement-induced membrane defect. They found the defect to vary slightly in size with the source of complement (on the average, the size was 8.8 nm with guinea pig complement and 10.3 nm with human complement), but the size and nature of the holes did not differ with various types of antigen-antibody systems or in PNH. In contrast, the number of holes per cell varied considerably and could be manipulated *in vitro* by appropriate adjustments of the concentration of the C2 component of complement. However, hemolysis occurred even if

the average number of holes was as low as 1.73 per cell, as had been predicted previously on the basis of kinetic studies.<sup>88</sup> It was concluded that if the number of holes is large enough, as it might be in anti-A or PNH hemolysis, effectively larger defects might be produced by tearing between holes or by superimposition of two or more lesions. Such larger defects might permit the diffusion of hemoglobin.

There is little evidence that complement is involved in the destruction of normal, senescent erythrocytes. Sensitivity of cells to antibody-complement lysis was found to increase with cell age, but the differences were slight.<sup>91</sup>

### Hemoglobin Denaturation

The sequence of events occurring when erythrocytes are exposed to oxidant stress is discussed in Chapter 3 (page 104), along with the mechanisms serving to protect the cell from this type of damage. If these mechanisms fail, denatured hemoglobin precipitates, forming inclusion bodies known as Heinz bodies. Cellular destruction usually follows Heinz-body formation, partly because the cells containing these inclusions become sequestered in the spleen where complete or partial phagocytosis takes place. In addition, the Heinz bodies may form disulfide linkages with membrane sulfhydryl groups, a phenomenon associated with increased membrane permeability and increased susceptibility to osmotic lysis.<sup>83</sup>

Heinz-body formation is the principal mechanism of hemolysis in G6PD deficiency and related disorders (Chapter 23), in unstable hemoglobin disease (Chapter 24), and in certain of the thalassemias (Chapter 26). There is no solid evidence that Heinz-body formation is a preterminal event in the normal red cell; however, this possibility is suggested by the facts that aged cells are deficient in G6PD<sup>34,35,37,47</sup> and that they contain certain hemoglobin derivatives that are precursors of Heinz bodies.<sup>44,48</sup>

## Sites of Erythrocyte Destruction

Approximately 80 to 90% of normal erythrocyte destruction occurs without release of hemoglobin into plasma.<sup>117,118,131</sup> Because of this fact, the major part of the destructive process is presumed to be *extravascular*, probably within macrophages of the reticulo-endothelial (RE) system. Only 10 to 20% of normal destruction occurs *intravascularly*, and this mode of destruction has special characteristics to be discussed below. Most hemolytic anemias are characterized by predominantly extravascular destruction; in some, usually called hemoglobinurias, intravascular destruction predominates.

### Extravascular Hemolysis

For many years, it was considered that the RE cells of the liver play the major role in the breakdown of red cells. This theory arose because the experiments of Minkowsky and Naunyn were conducted in ducks and geese, animals in which the RE system is made up almost entirely of the hepatic Kupffer cells. In man the fixed macrophages of the RE system are more widely distributed. It is clear that other organs, especially the spleen, participate in erythrocyte destruction and that even in contused wounds, or in subcutaneous tissues into which erythrocytes have been injected, erythrocyte breakdown occurs.<sup>129</sup>

The relative importance of the spleen and liver in erythrocyte destruction is influenced by the degree of cell damage.<sup>90</sup> Severe degrees of damage lead to destruction in all parts of the RE system, but especially in the liver because of its relatively great blood flow. In contrast, when erythrocytes are injured less severely, destruction occurs in the spleen.<sup>74</sup> It is probable that effete red cells are destroyed primarily in the spleen; however, if this organ is removed from normal subjects, other parts of the RE system rapidly assume this function, and there is no increase in cell survival.<sup>135</sup> The erythroclastic func-

tion of the spleen and RE system is discussed in more detail in Chapter 8 (page 363).

### Intravascular Hemolysis

Special features characterize those situations in which red cells are destroyed within the circulation rather than within the RE cell. When this happens, hemoglobin is discharged directly into the circulation from which it is removed by several mechanisms (Fig. 5-4).

#### *Haptoglobin*<sup>118,121</sup>

At low rates of release of hemoglobin into plasma, all of the hemoglobin is found to be attached to haptoglobin. This specific, hemoglobin-binding protein was first detected in plasma by its ability to enhance the peroxidase activity of hemoglobin.<sup>134</sup> Since its concentration was found to increase in a variety of inflammatory diseases, this was recognized as a nonspecific sign of disease with much the same significance as an accelerated sedimentation rate (page 127). The role of haptoglobin as a hemoglobin-binding protein and as the principal factor affecting the "renal threshold" for hemoglobin was described by Laurell and Nyman.<sup>124</sup>

Haptoglobin is an  $\alpha_2$ -glycoprotein. By starch gel electrophoresis, a number of haptoglobin bands may be demonstrated. The observed pattern reflects the genetic constitution.<sup>139</sup> There are two principal, allelic, autosomal genes, Hp1 and Hp2, neither of which is dominant. These result in three principal phenotypes, Hp1-1, Hp2-2, and Hp2-1 (Fig. 5-5). The incidence of these phenotypes in white Americans is 15%, 38%, and 47%, respectively. There also are subgroups of these basic types; two normal varieties of the Hp1 gene have been distinguished, namely, Hp1F and Hp1S. Rare genetic variants of the common genes also have been reported.<sup>115,121</sup> The haptoglobin in individuals of phenotype Hp1-1 is a single molecular species with a molecular weight of about 85,000. The molecule resembles that of certain immunoglobulins in that it has two

"light" ( $\alpha$ ) chains and two "heavy" ( $\beta$ ) chains. In individuals of phenotype Hp2-2 and Hp2-1, a number of haptoglobin bands are found (Fig. 5-5), and these appear to be polymers of a basic subunit similar in size to Hp1-1. The genetic variation affects the "light" ( $\alpha$ ) chains only; the heavy chains appear to be identical in all phenotypes.

The normal plasma haptoglobin concentration is  $1.28 \pm 0.25$  g/l.<sup>122</sup> More often, the concentration is expressed in terms of the hemoglobin-binding capacity. The normal values for the latter differ with phenotype: for Hp1-1,  $1.36 \pm 0.37$  g/l; for Hp2-1,  $1.08 \pm 0.37$  g/l; and for Hp2-2,  $0.82 \pm 0.34$  g/l.<sup>132</sup> If phenotype is disregarded, the normal range is 0.4 to 2.0 g/l.<sup>118</sup> The association constant between haptoglobin and hemoglobin is so great that the reaction may be considered irreversible. Haptoglobin (Hp) is able to bind oxyhemoglobin (Hb), methemoglobin, isolated Hb  $\alpha$ -chains,  $\alpha\beta$  dimers and heme-free globin, but it will not bind deoxygenated hemoglobin, myoglobin, heme, hemoglobin H or Barts, or isolated Hb  $\beta$ -chains. The binding site on Hb is thought to be on the  $\alpha$ -chain and the binding site on Hp is probably on its heavy ( $\beta$ ) chain.<sup>119</sup> The chemical nature of the bond is unknown.

In most instances, the molar ratio of Hp to Hb in the HpHb complex is 1:1 if a reference molecular weight of 85,000 for haptoglobin is used to correct for polymerization.<sup>141</sup> It has been observed that with horse Hb at least three different types of HpHb complexes are formed in vitro and the relative proportions of each depend on the ratios of hemoglobin and haptoglobin present.<sup>141</sup> These three complexes, which differ in the degree to which the Hb molecule has dissociated, have been designated HpHb, Cx, and Cd. In HpHb, one Hb  $\alpha\beta$  dimer, one Hb  $\alpha$ -chain, and one Hb  $\beta$ -chain are bound; in Cx, two  $\alpha$ -chains and two  $\beta$ -chains are bound; and in Cd, one  $\alpha$ - and one  $\beta$ -chain are bound. Others, however, have found that if only human hemoglobin is added, a comparable series of complexes is not found;

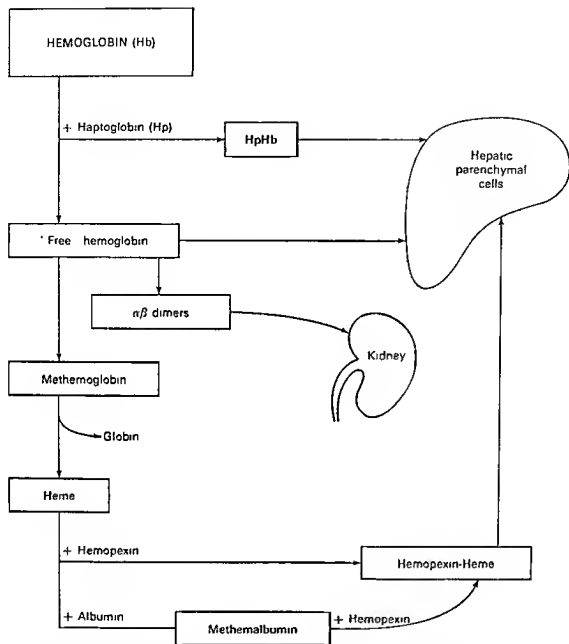

Fig 5-4 Pathways for the disposal of hemoglobin (Hb) in plasma. The initial pathway is through binding by haptoglobin (Hp) with subsequent removal of the HbHp complex by hepatic parenchymal cells.<sup>123</sup> Hemoglobin in excess of the Hp binding capacity circulates as the unbound (free) protein. In this form it is partially removed by hepatic cells, but it may also follow two other pathways. It may dissociate into two half molecules ( $\alpha\beta$  dimers) that are excreted by the kidney. In addition, it may be oxidized to methemoglobin, from which heme is easily dissociated. The latter is initially bound to hemopexin, which transports it to the hepatic parenchymal cell. Heme may also be bound nonspecifically by albumin, forming methemalbumin. This complex transfers its heme to hemopexin as the latter becomes available.

Fig 5-5. Starch gel electrophoretic patterns of the common haptoglobin (Hp) phenotypes. The three major phenotypes (left) can be subdivided on the basis of analysis of the light (a) polypeptide (right). (From Giblett,<sup>118</sup> courtesy of the author and Williams & Wilkins Company.)

instead, two  $\alpha\beta$  dimers are bound symmetrically to each Hp molecule.<sup>127</sup>

Haptoglobin is synthesized in the parenchymal cells of the liver.<sup>112,128</sup> When not bound to hemoglobin, it leaves the plasma with a half-disappearance time of about five days. The HpHb complex leaves much more rapidly with a half-disappearance time of about nine minutes. About 50 to 80% of the haptoglobin turnover in the normal subject is accounted for by the rapid pathway.<sup>131</sup> The hepatic parenchymal cell appears to be the main site of removal of the HpHb complex.<sup>113</sup> From the kinetics of haptoglobin turnover it may be calculated that some 10 to 20% of normal erythrocyte destruction occurs intravascularly and utilizes the haptoglobin system.<sup>118,131</sup> Since a portion of any unbound hemoglobin is excreted into the urine, it is reasonable to infer that the normal physiologic function of haptoglobin is to prevent renal loss of hemoglobin, thereby conserving iron and protecting the renal tubular cells from damage.<sup>111</sup> In hemolytic anemias characterized by intravascular hemolysis, catabolism of Hp is so rapid that it essentially disappears from the plasma, a change that is not accompanied by a compensatory increase in haptoglobin synthesis. Hypohaptoglobinemia may also be observed in certain hemolytic states associated with predominantly extravascular destructive mechanisms.<sup>118</sup> The explanation for this is

not clear, but it has been suggested that some hemoglobin may be regurgitated from RE cells when the rate of phagocytosis of erythrocytes or erythrocyte fragments reaches a maximum.<sup>158</sup>

#### *Hemoglobin and the Kidney<sup>133</sup>*

The hemoglobin-haptoglobin complex is too large (molecular weight about 150,000) to pass through the glomerulus. Thus, the level of circulating haptoglobin is the most important determinant of the apparent renal threshold.<sup>121</sup> When the haptoglobin system is saturated, free (unbound) hemoglobin circulates briefly in plasma. The hepatic parenchymal cell is partially responsible for the disposal of free hemoglobin,<sup>113</sup> but, in addition, hemoglobin dissociates into two  $\alpha\beta$  dimers which, having a molecular weight of about 32,000, readily pass through the glomerulus.<sup>113</sup> There is a low (0.2 to 0.6 g/l) renal threshold for free hemoglobin that is related to renal tubular reabsorption rather than to haptoglobin.<sup>123</sup>

Much of the hemoglobin appearing in the glomerular filtrate is reabsorbed in the proximal tubule.<sup>123</sup> The rate of tubular reabsorption of hemoglobin in adult males is  $1.43 \pm 0.96$  mg/min.<sup>126</sup> If this capacity is exceeded, hemoglobin appears in the urine. Thus, renal handling of hemoglobin is similar

to that of glucose, urate, and certain other substances.<sup>115</sup>

Within the tubular epithelial cell, hemoglobin iron is rapidly extracted and stored in the cell as ferritin and hemosiderin.<sup>115,136</sup> Some of the tubular epithelial iron may be reutilized for hemoglobin synthesis, but only at a very slow rate.<sup>115</sup> When iron-laden tubular cells are sloughed into the urine, the urine iron concentration increases and both ferritin and hemosiderin may be detected.<sup>136</sup>

### Plasma Heme

Free hemoglobin in plasma may be readily oxidized to methemoglobin. The latter dissociates easily and nonenzymatically into heme and globin.<sup>114</sup> Free heme is highly insoluble at physiologic pH, but two serum proteins, hemopexin and albumin, are able to bind it and maintain it in a soluble form. *Hemopexin*,<sup>130</sup> a  $\beta_1$ -globulin, is a glycoprotein with a molecular weight of about 70,000, of which 20% is carbohydrate. It is synthesized in the liver<sup>140</sup> and is found in the plasma of adults in a concentration of 50 to 100 mg/dl. Each hemopexin molecule binds one molecule of heme and may also bind certain porphyrins, but not bile pigments. The hemopexin-heme complex is removed from the circulation by the hepatic parenchymal cell, with a half-disappearance time of seven to eight hours.<sup>130</sup> Like haptoglobin, hemopexin is depleted as it serves its function.<sup>130,137</sup> Plasma hemopexin values may be reduced in conditions associated with intravascular hemolysis, but the depletion is less regular and less pronounced than that of haptoglobin. Especially low hemopexin values are found in thalassemia major and sickle cell anemia.<sup>130</sup>

Albumin binds heme in a 1:1 molar ratio<sup>125</sup> to form methemalbumin.<sup>116</sup> The affinity of albumin for heme is much less than that of hemopexin.<sup>130</sup> Methemalbumin may be detected by its spectral properties and by the formation of a hemochromogen with a sharply defined absorption band at 558 nm in the presence of ammonium sulfide (Schumm's test). This test was formerly considered to be specific for methemalbumin;

however, hemopexin-heme forms a similar chromogen.<sup>135</sup> The disappearance of methemalbumin from the circulation is kinetically complex, but it is clearly slower than that of hemopexin-heme.<sup>137</sup> It is possible that methemalbumin follows no specific disposal pathway, but, instead, gradually transfers its heme to hemopexin as the latter becomes available.<sup>130</sup>

## Hemoglobin Catabolism<sup>178,191</sup>

### Formation of Bilirubin

About 30 minutes after injection of either hemoglobin or nonviable red cells, there is an increase in bilirubin in serum and bile as well as in iron entering plasma and in carbon monoxide, derived from the  $\alpha$ -methene carbon of heme,<sup>159,160</sup> exhaled from the lungs. Studies of the nonenzymatic oxidation of hemoglobin with oxygen and ascorbate led Lemberg to believe that the first step in hemoglobin catabolism was the opening of the porphyrin ring by oxidation of the  $\alpha$ -methene bridge, the iron remaining and the union with globin persisting to form a green, iron protein compound, verdohemoglobin or choleglobin.<sup>176,177</sup> The discovery of an enzyme system that converts heme to bilirubin has led to revision of this concept.<sup>191</sup>

The enzyme, microsomal heme oxygenase, catalyzes the degradation of heme to iron, carbon monoxide, and a greenish pigment, biliverdin (Fig. 5-6). Since the substrate for this reaction is heme, not hemoglobin, dissociation of heme from globin must be presumed to precede the reaction. The enzyme is found in the microsomal fraction of homogenates of a number of organs. Activity is greatest in spleen, followed by bone marrow, liver, brain, kidney, and lung. Microsomal heme oxygenase appears to be inducible by its substrate, since activity is markedly increased by the prior injection of methemalbumin as well as by injection of hemoglobin or by induction of hemolytic anemia. Also, splenectomy is followed by a two- to three-fold increase in enzyme activity in the liver,<sup>194</sup> and hemoglobinuria is associated

Fig. 5-6. Enzymatic degradation of heme to form iron (Fe), carbon monoxide (CO), and bilirubin. The porphyrin ring is cleaved by oxidation of the  $\alpha$ -methene bridge (a). The reaction depends upon an enzyme, microsomal heme oxygenase, and requires oxygen and nicotinamide adenine dinucleotide phosphate (NADPH) as cofactors. In addition, an abbreviated electron transport system is utilized, which includes cytochrome P-450 ( $P_{450}$ ) and a flavoprotein (Fp). Biliverdin is reduced to bilirubin by NADPH in a reaction catalyzed by biliverdin reductase. Side chains of heme and the bile pigments are abbreviated as follows: M, methyl; V, vinyl; P, propionate. (From Tenhunen et al.<sup>194</sup> courtesy of the authors and Transactions of Association of American Physicians.)

with induction of the enzyme in renal tubular cells.<sup>133</sup> Enzyme induction has also been observed in vitro in peritoneal macrophages.<sup>78</sup> In such preparations, heme oxygenase activity increased dramatically about three hours after erythrophagocytosis. Induction was blocked with puromycin, actinomycin D, and hydrocortisone, but the hydrocortisone effect could be prevented with glucose and insulin.

The heme oxygenase reaction is coupled with a second step in which biliverdin is reduced to bilirubin (Fig. 5-6). This reaction is catalyzed by a soluble, NADPH-dependent enzyme, biliverdin reductase. The system converting heme to bilirubin is classed with a group of similar enzymes termed "mixed-function" oxidases, which are characterized by the utilization of an abbreviated, microsomal electron transport system with cytochrome P-450 as the terminal oxidase. The stoichiometry of the reactions is such that three moles of oxygen and probably four moles of NADPH are utilized for each mole of bilirubin and carbon monoxide formed.

The bilirubin formed in vitro by this sys-

tem is of the isomer type that occurs naturally in vivo. This isomer is designated IX  $\alpha$  to indicate that it has the side chain structure of protoporphyrin IX and that cleavage of the porphyrin ring takes place at the  $\alpha$ -methene bridge. In contrast, a mixture of bilirubin isomers is synthesized in the system described by Lemberg.<sup>191</sup> The only known endogenous source for carbon monoxide is in the microsomal heme oxygenase reaction.<sup>160</sup> Consequently, measurement of endogenous carbon monoxide production may be used as a measure of the rate of red cell destruction (page 216).

If isotopically labeled glycine is administered to a normal person, the label is incorporated into the porphyrin ring and ultimately makes its appearance in bilirubin<sup>140</sup> (Fig. 5-7). The label appears in about 85% of bilirubin at about 120 days after administration of the isotope and therefore is presumed to be derived from the destruction of senescent red cells; the remaining 15% of the pigment is labeled within several days and hence is often referred to as the "early-

Fig 5-7. The incorporation of isotopically labeled glycine into heme and bile pigments. Most of the bilirubin labeling occurs at about 120 days, at the time of destruction of senescent red cells. However, about 15% of bilirubin is labeled within the first several days and is therefore called the "early-labeled" fraction.

labeled" bilirubin. This fraction is made up of at least two components.<sup>172,190</sup> The first, normally the larger one, is labeled maximally at 24 hours and is of hepatic origin, probably chiefly from the heme of cytochrome P-450. The second is labeled maximally at about three to four days and is a by-product of erythropoiesis.<sup>154,172</sup> An isotopic label from administered aminolevulinic acid appears primarily in the hepatic fraction, whereas that from glycine appears in both.<sup>190</sup> The erythropoietic component is probably the product of "ineffective erythropoiesis" (page 550), and results from the intramedullary destruction of defective red cells. In illnesses associated with exaggerated ineffective erythropoiesis, such as thalassemia or pernicious anemia, there is a marked increase in the "early-labeled" bilirubin fraction.

### Bilirubin Transport

After being released from the sites of heme catabolism, bilirubin appears in plasma. The normal value for plasma bilirubin is usually given as 0.5 to 1.0 mg/dl; however, some

studies have suggested that the distribution of values in a normal population is skewed and up to 1.5 mg/dl may be within normal limits.<sup>196</sup> Being poorly soluble in water, bilirubin carried in plasma must be bound to albumin, which greatly increases its solubility. Each molecule of albumin is able to bind two molecules of bilirubin, the first molecule being more tightly bound than the second.<sup>184,186</sup> At normal plasma albumin concentrations, the theoretical bilirubin-binding capacity is of the order of 70 mg/dl, of which half, or 35 mg/dl, is tightly bound. These values are reduced by a decrease in plasma albumin concentration or by the presence of organic, anionic substances that compete for albumin-binding sites, such as heme, fatty acids, sulfonamides, and salicylates. When the binding capacity is exceeded, bilirubin diffuses into the tissues, especially tissues with a high lipid content.

Under certain pathologic circumstances, bilirubin diglucuronide (conjugated bilirubin, "direct-reacting" bilirubin) is found in the plasma. This relatively soluble bilirubin derivative may also be bound to albumin, but

less tightly so than the unconjugated form. Some of the plasma bilirubin diglucuronide is ultrafilterable, being bound to an unidentified material of low molecular weight.<sup>166,167</sup> This complex passes through the glomerulus, is not reabsorbed in the tubule, and thus is excreted into the urine. In contrast, unconjugated bilirubin is not excreted by the kidney.

### Hepatic Bilirubin Metabolism

The processing of bilirubin by the liver may be thought of as only one aspect of a general mechanism whereby plasma protein-bound, organic anions are metabolized

and excreted. In addition to bilirubin, other anionic substances follow the same pathways, especially certain dyes (eg, bromosulfalein or BSP), cholecystographic agents, drugs (eg, salicylates), steroids, and thyroxine. The process may be divided into three distinct phases: uptake, conjugation, and excretion<sup>151</sup> (Fig. 5-8). All three phases must be operative if bilirubin is to be excreted at a normal rate; however, in the normal person the excretion step is the slowest, and therefore the rate-limiting, step.

Relatively little is known about the mechanism of hepatic *bilirubin uptake*. However, it is clear that the process is rapid and efficient. In rats, for example, 65% of an admin-

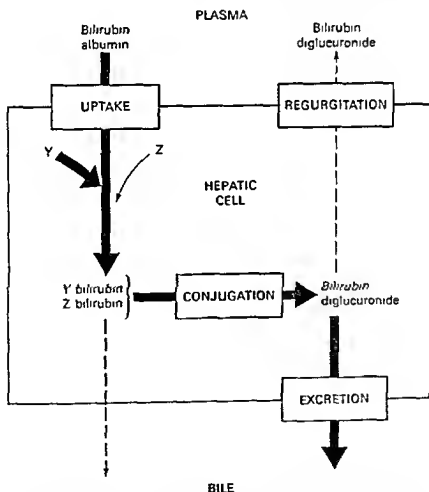

Fig 5-8. Normal and abnormal pathways of bilirubin excretion by the hepatic cell. The normal pathways (solid arrows) include uptake and conjugation of bilirubin and excretion of the conjugated derivative. Abnormal pathways (dashed arrows) include regurgitation of bilirubin diglucuronide into plasma and excretion of unconjugated bilirubin into bile. Y and Z are bilirubin-binding proteins that may play a role in the uptake step.

istered dose of bilirubin is taken up by the liver within five minutes. There are two viewpoints regarding the mechanism of hepatic uptake. One of these holds it to be a function of the hepatocyte plasma membrane, and to be a carrier-mediated, active transport process, perhaps involving specific membrane receptor sites.<sup>178</sup> To date, there is little evidence to support or refute this hypothesis. However, the discovery of two bilirubin-binding proteins, designated Y and Z, in hepatocyte cytoplasm<sup>179</sup> has led to the alternate proposal that hepatic uptake is a function of these intracellular binding proteins.<sup>152</sup> Y protein, which has been isolated in pure form, constitutes about 5% of hepatic, cytoplasmic protein.<sup>152</sup> Structurally, it is a 44,000 molecular weight dimer formed from two identical 22,000 molecular weight subunits. Z protein, which has been only partially purified, is present in smaller amounts than Y; it has a molecular weight of 9000 to 10,000. Administration of certain drugs, notably phenobarbital, brings about a threefold increase in the concentration of Y, but Z is unaffected.<sup>188</sup> Both Y and Z proteins bind many organic anions in addition to bilirubin.<sup>152</sup> It is proposed that bilirubin, bound to albumin, is presented to the hepatocyte membrane, where it dissociates from albumin and crosses the membrane by non-ionic diffusion. A rapid, bidirectional flux between plasma and liver ensues,<sup>168</sup> the net hepatic uptake being determined by the amount and binding affinity of albumin in the plasma and the amount and binding affinity of Y and Z protein in the cytoplasm.<sup>152</sup> The unconjugated hyperbilirubinemia that occurs in patients given flavaoidic acid, an agent used in treatment of certain tapeworm infestations, has been ascribed to competition between the drug and bilirubin for binding sites on the Z protein.<sup>152,183</sup> On the basis of indirect evidence, it has been suggested that the abnormality in a proportion of patients with Gilbert's syndrome<sup>189</sup> (idiopathic unconjugated hyperbilirubinemia) is impaired hepatic uptake of bilirubin.<sup>156</sup> As yet, the amounts and binding affinities of Y and Z proteins in this syndrome have not been investigated.

Having entered the liver cell, bilirubin is *conjugated* with two molecules of glucuronic acid to form bilirubin diglucuronide. The reaction is catalyzed by uridine diphosphate (UDP)-glucuronyl transferase, an enzyme associated with the endoplasmic reticulum membrane.<sup>152,175</sup> Proliferation of endoplasmic reticulum and markedly increased activity of UDP-glucuronyl transferase occur after administration of phenobarbital and certain other drugs.<sup>203</sup> In the conjugation reaction, glucuronic acid, a derivative of glucose, is transferred from UDP-glucuronic acid to the propionyl carboxyl groups of bilirubin to which it becomes attached through ester linkages, forming bilirubin diglucuronide. It is uncertain whether all these reactions are catalyzed by the same enzyme system or if there are several glucuronyl transferases. Traces of bilirubin may be conjugated with sulfate<sup>173</sup> rather than glucuronide, but little is known about this pathway and it is not likely to be of functional importance.<sup>178</sup> Bilirubin diglucuronide is considerably more polar and water-soluble than unconjugated bilirubin. In hepatocellular disease or biliary obstruction, it may be "regurgitated" into plasma. Normally, it is excreted into the bile. Little or no unconjugated bilirubin is found in bile, and if conjugation does not occur, bile bilirubin content is very low. Hereditary lack of UDP-glucuronyl transferase leads to severe jaundice in the "Gunn" rat.<sup>157,170</sup> It is probable that the rare, human illness, the Crigler-Najjar syndrome,<sup>161</sup> is the human equivalent of the same defect.<sup>167,178</sup> One form of Gilbert's syndrome may result from mild UDP-glucuronyl transferase deficiency.<sup>153</sup> Jaundice in this syndrome is relieved by phenobarbital, presumably because of its effects on enzyme concentration.

*Excretion* of conjugated bilirubin from the hepatic cell into the bile canaliculus is generally considered to be an active transport process, since it proceeds against large concentration gradients. It is the least understood aspect of hepatic bilirubin metabolism. Neither the energy source nor a specific carrier has been identified.<sup>152</sup> It has been suggested

that the Golgi apparatus is involved.<sup>152</sup> The Dubin-Johnson syndrome<sup>162</sup> probably results from a defect in cellular excretion of bilirubin and certain other organic anions.<sup>151,178</sup>

### Intestinal Bile Pigment Metabolism<sup>163,178</sup>

Bilirubin diglucuronide is excreted into the duodenum with other constituents of bile. There is little or no intestinal absorption of the conjugated pigment, although unconjugated bilirubin is readily absorbed. Bilirubin diglucuronide probably remains in the conjugated form until it reaches the terminal ileum and colon where bacterial  $\beta$ -glucuronidases hydrolyze it. The two methene ( $-\text{CH}=\text{}$ ) bridges and usually the two vinyl groups are then reduced by bacterial flora to form a series of compounds called *urobilinogens*<sup>197</sup> (Fig. 5-9). These are colorless compounds that react with Ehrlich's aldehyde reagent to form a red-violet chromogen. Since urobilinogen formation is accomplished by bacteria, it does not occur in newborn or

in germ-free animals,<sup>171</sup> and it may be markedly affected by administration of broad-spectrum antibiotics.<sup>197</sup> The urobilinogens are easily dehydrogenated across the two middle rings to form *urobilins* (Fig. 5-9). The latter differ from urobilinogens in that they are colored (orange-yellow) and do not react with Ehrlich's reagent. Urobilins are characterized further by their ability to react with zinc to form fluorescent (green) compounds (Schlesinger reaction).

About 10 to 20% of the urobilinogen formed in the gut is reabsorbed and the remainder is lost with the feces. The reabsorbed fraction is efficiently excreted by the normal liver without being conjugated.<sup>178</sup> This sequence of events is referred to as the enterohepatic recirculation of urobilinogen. A portion of the reabsorbed pigment may also be excreted into the urine. Urobilinogen is filtered by the glomerulus, secreted by the renal tubule, and reabsorbed. Tubular reabsorption is facilitated in acid urine; therefore, renal clearance is greatest when the

Fig 5-9. Bile pigment metabolism in the gut. These reactions are carried out by bacteria. d-Urobilinogen, mesobilirubinogen and stercobilinogen are members of the urobilinogen group, which is characterized structurally by saturation of the carbon bridges connecting the pyrrole rings. The urobilins are derived from urobilinogens by oxidation and have one or more double bonds in the connecting carbon bridge. (From Lester and Troxler,<sup>178</sup> courtesy of the authors and Gastroenterology.)

urine is alkaline. If the liver's capacity to excrete urobilinogen is impaired a disproportionate amount appears in the urine.

Also found in the colon are a group of poorly characterized dipyrroles known as mesobilifuscins. These brown pigments are partly responsible for the color of normal feces.<sup>202</sup> Most of these dipyrroles do not appear to be derived from the degradation of bilirubin; instead, they probably are anabolic by-products of heme synthesis.<sup>168</sup> However, in conditions associated with Heinz-bodies (Chapters 23, 24, and 26), excessive amounts of such dipyrroles are excreted in the urine. These are thought to be derived from the heme released when the Heinz body forms (page 817). Furthermore, a dipyrrole is formed from the photodegradation of bilirubin,<sup>183</sup> as discussed in the following section.

#### Alternate Pathways of Heme and Bilirubin Catabolism

On a strictly stoichiometric basis, it may be calculated that 35 mg of bilirubin should be produced from the quantitative destruction of 1 g of hemoglobin. Assuming a normal red cell survival of 120 days, the daily excretion of bilirubin and urobilinogens should be 28 mg per 100 g circulating hemoglobin per day, even if there were no contribution from nonerythroid pathways. In normal subjects, however, only 11 to 21 mg/100 g hemoglobin/day are excreted.<sup>182</sup> These observations imply that as much as 20 to 40% of heme may be degraded by pathways other than bilirubin,<sup>198</sup> or that bilirubin itself may be converted to catabolites other than urobilinogen or urobilin.

The existence of such alternate pathways was demonstrated experimentally when only 60 to 80% of the radioactivity in administered labeled heme, hemoglobin, or damaged erythrocytes could be accounted for as bilirubin collected from rats with biliary fistulas.<sup>174,187</sup> Radioactivity in unidentified, non-bilirubin components of bile was found in such animals.<sup>174</sup> Furthermore, in severe, inherited defects of bilirubin conjugation, such as those

found in the Gunn rat or in human infants with the Crigler-Najjar syndrome, the alternate pathways appear to be increased.<sup>192</sup>

It is possible that some of these observations can be explained by a series of reactions whereby bilirubin is converted to a variety of water-soluble derivatives, including hydroxyrubins, bilichrysin, and a dipyrrole.<sup>185</sup> These conversions are accompanied by loss of yellow color and diazo reactivity, and are accelerated in vitro and in vivo by exposure to light. Similar or identical reactions occur in vitro in the dark in alkaline, aqueous solutions. Products of the reaction are found in the bile of the Gunn rat.

These photodegradation reactions of bilirubin have been applied to the treatment of unconjugated hyperbilirubinemia in infants.<sup>181</sup> Exposure to light brings about a prompt decrease in serum bilirubin concentration to non-toxic levels. The photodegradation products are excreted promptly in the bile and may cause the stool to turn to a green or darker brown color. No toxicity of these products has been demonstrated, but only short-term observations are currently available.

#### Laboratory Evaluation of Hemoglobin Catabolism and Bile Pigments

##### *Icterus Index (Meulengracht Test)*

Determination of the icterus index is a very simple procedure for the rough quantitation of the degree of yellowish coloring of the plasma or serum. Comparison is made with the color of standard solutions of potassium dichromate made up in a series of tubes numbered according to the quantity of dichromate in 10,000 parts of water; thus, 1 unit is 1:10,000, 5 is 5:10,000, and so on.

The simplest procedure is to compare the color of the plasma, as seen in the Wintrobe hematocrit after it has been centrifuged, with that of a series of standards in tubes of glass of the same thickness and bore as the hematocrit (Fig. 5-10 and Frontispiece). If the icterus index is greater than 100, the plasma may be diluted until a match is obtained.

Fig. 5-10. Icterus index and blood sedimentation apparatus for use in conjunction with hematocrit. The standard icterus index tubes are shown on the right. The unknown is matched against the standards in the central portion of the block. The section at the front of the block is for holding hematocrits vertically during sedimentation.

The icterus index is a useful, simple, and rapid test. When it is normal (5 to 7.5 units) it can be assumed that there is no increase in the bilirubin content of the blood stream. The test is important during a routine blood examination in calling attention to the presence of unsuspected hyperbilirubinemia. It must be borne in mind that it is not specific and that substances other than bilirubin may cause an increase in the yellow color. Of these substances the lipochromes (carotene, lutein, etc.) are the most important. Thus, in vegetarians, diabetics, infants, and patients with myxedema there may be an increased icterus index that is not the result of hyperbilirubinemia. The drug atabrine may occasionally be sufficiently concentrated in the blood to cause an elevation in the icterus index.

#### *van den Bergh Test*

As distinguished from the icterus index, the van den Bergh test is a specific test for bilirubin. It is based on Ehrlich's discovery that a mixture of sulfanilic acid, hydrochloric acid, and sodium nitrite (diaz reagent) yields a reddish-violet color with a maximum absorption at a wavelength of 430 nm when added to plasma or other solutions containing bilirubin. The color may appear and reach its maximum intensity at once ("direct" reaction); if no color develops in one minute, alcohol is added. If the color then appears,

the reaction is called "indirect." In general, unconjugated bilirubin is indirect-reacting and bilirubin diglucuronide is direct-reacting. However, because of the kinetics of the van den Bergh reaction and the presence of solubilizing substances in the plasma, the direct and indirect test yields only approximations of the respective concentrations of bilirubin diglucuronide and of bilirubin. The difference between the reactivity of conjugated and unconjugated bilirubin has been ascribed to relative water solubility of the two compounds; however, a more plausible explanation is the difference in hydrogen bonding within the molecules and the resulting steric interference with access of the diazo reagent to the central methene group.<sup>165</sup>

#### *Tests for Urobilinogen and Urobilin*

Practical tests for urobilinogen and urobilin are based on Ehrlich's aldehyde reaction. When Ehrlich's reagent (paradimethylaminobenzaldehyde) reacts with a member of the urobilinogen group, a red-violet chromogen (maximum absorption wavelength, 565 nm) is formed. Urobilin is Ehrlich negative, but if it is first reduced to urobilinogen with ferrous sulfate in sodium hydroxide, a positive reaction is obtained. The reaction is not specific for urobilinogen.<sup>163</sup> Monopyrroles, such as porphobilinogen (page 170), indoles, and certain other substances form similar pigments. In addition, some indicator dyes (eg, pyridium) turn red when exposed to the acid in Ehrlich's reagent.

Semiquantitative assays for urobilinogen that are of practical value have been devised by Watson et al.<sup>209</sup> For serial observations of urine urobilinogen, a two-hour sample is collected between 2 and 4 P.M. following emptying of the bladder and drinking one glass of water. During this period of the day the peak excretion of urobilinogen usually occurs. The sample is cooled to room temperature and examined within 30 minutes after voiding. Normal values for the two-hour period range from 0.1 to 1.5 "Ehrlich units," which are approximately equivalent to 1 mg of urobilinogen. The term "unit" is

used because the method is not specific for urobilinogen; other Ehrlich-reacting substances are measured as well. The increase of these other substances has been found to be roughly proportional to that of urobilinogen and consequently the test is useful for serial observations. It has been found to give false negative results in about 15% of patients with significant degrees of hyperurobilinogenuria.<sup>195</sup>

A *semiquantitative method* may also be used on random fecal specimens.<sup>200</sup> The upper limit of normal is about 350 Ehrlich units per 100 g. The *quantitative method* is discussed on page 217.

### *The Rate of Heme Catabolism*

As discussed elsewhere in this chapter (page 209), the principal catabolic products of heme are iron, carbon monoxide, and bilirubin. There are no other significant endogenous sources of the last two compounds; thus, the breakdown of one mole of heme yields precisely one mole of carbon monoxide and one mole of bilirubin. Measurements of the endogenous production of carbon monoxide or bilirubin constitute accurate assessments of the rate of heme catabolism. The methodology is complex, however, and, for the most part, such measurements have been performed in research settings. More available to clinicians is the determination of fecal urobilinogen excretion—an older, less accurate approach to quantitation of heme breakdown.

From any of these measures of the rate of heme catabolism together with the determined or estimated circulating red cell volume, the erythrocyte life span can be estimated.<sup>155</sup> Such estimates are based on the assumption that about 85% of the heme broken down comes from the destruction of circulating red cells (page 209). This assumption is valid except in those conditions associated with ineffective erythropoiesis. Consequently, the demonstration that the amount of heme catabolized exceeds that which can be accounted for on the basis of a simultaneously performed study of erythro-

cyte life span constitutes excellent evidence for ineffective erythropoiesis.

**ENDOGENOUS CARBON MONOXIDE (CO) PRODUCTION.** Sjostrand<sup>193</sup> and, later, Engstedt<sup>164</sup> called attention to the fact that blood carboxyhemoglobin (COHb) levels are increased in hemolytic disease. Precise interpretation of such static measurements is complicated by exogenous exposure to CO and by variations in CO excretion. In contrast, however, the endogenous rate of CO production ( $\dot{V}_{CO}$ ) can be measured by a re-breathing method that circumvents these problems.<sup>160</sup> The subject breathes into a closed system from which CO<sub>2</sub> is absorbed and to which O<sub>2</sub> is added. CO excretion is thereby prevented and the blood level of COHb increases. Endogenous CO production is calculated from the rate of increase over a two-hour period and from the body CO dilution. The latter is determined by adding a small quantity of CO to the re-breathing system and measuring the resultant increase in blood COHb.

With this method, the average normal value for  $\dot{V}_{CO}$  was found to be  $18.7 \pm 3.2$  (SD)  $\mu\text{mol/hr}$ . In eight patients with various types of hemolytic anemia, the values ranged from 31 to 143  $\mu\text{mol/hr}$  or about 1.5 to 8 times normal.<sup>159</sup> In five subjects with conditions associated with ineffective erythropoiesis, values from 21 to 94  $\mu\text{mol/hr}$  were found.<sup>201</sup>

**BILIRUBIN PRODUCTION.** The rate of bilirubin production can be calculated from the kinetics of plasma bilirubin disappearance.<sup>153</sup> A tracer dose of <sup>3</sup>H- or <sup>14</sup>C-bilirubin is injected intravenously, the bilirubin pool size is measured, and serial determinations of plasma unconjugated radioactive bilirubin are made over a 24- to 48-hour period. The disappearance curve is complex and requires analysis by digital computer. The curve appears to be the sum of three exponential components with normal average half-disappearance times of 18, 81, and 578 minutes, respectively. From the computer-analyzed data the normal bilirubin production rate in 13 normal subjects was

calculated to be  $3.8 \pm 0.6$  (SD) mg/kg/day.<sup>155</sup> Generally higher rates of bilirubin production were observed in hemolytic states and the data were expressed in terms of a calculated erythrocyte life span.<sup>155</sup> The results correlated well with other means of measuring erythrocyte life span.

**QUANTITATIVE EXCRETION OF UROBILINOGEN.** Quantitative fecal urobilinogen methods have been in use for some time and are employed in a number of clinical laboratories. They entail the timed collection of fecal specimens, usually over a four-day period. The average per diem excretion is determined from analysis of these specimens by methods based on the Ehrlich reaction<sup>199</sup> (page 215). Obviously, inaccuracies may be introduced by incomplete or inaccurately timed collections. Even if collection is adequate, there are reasons for considering urobilinogen excretion to be an imperfect index of heme breakdown (page 214).

The normal value for urobilinogen excretion is 40 to 280 mg/day.<sup>199</sup> However, this value is often expressed and better understood in relation to the estimated circulating hemoglobin mass<sup>182</sup> (page 727). Expressed in this relation, normal values of 11 to 21 mg per 100 g circulating hemoglobin have been observed; in hemolytic disease, values may be two to ten times greater.

## **Morphology and Chemical Properties**

Evidence for the replenishment of marrow and blood cells from a stem cell compartment was presented in Chapter 2. The multipotential, colony-forming unit cell (CFU or uncommitted stem cell) and the intervening ("committed") stem cells for each cell line have not been identified morphologically by traditional methods, and reliable electron microscopic criteria for distinguishing myeloblasts from pronormoblasts or lymphoblasts also are lacking.<sup>57,62,68,73</sup> Only the more mature forms of each hematopoietic cell series can be reliably distinguished from one another. In the following pages these cells will be described and their properties and functions will be considered.

### **The Myeloid Series**

Neutrophilic, eosinophilic, and basophilic granulocytes comprise the myeloid series. All three cell lines are thought to follow similar patterns of proliferation, differentiation, maturation and storage in the bone marrow, and delivery to the blood. The details of these processes are best documented for neutrophils and are meager for basophils. The first three morphologic stages, the myeloblast, promyelocyte, and myelocyte, are capable of replication as is shown by their uptake of tritiated thymidine and the presence of mito-

ses; the later stages cannot divide but undergo differentiation and maturational changes. The morphologic boundaries of each cell compartment were defined many years ago and were based on criteria such as cell size, ratio of size of nucleus to cytoplasm, fineness of nuclear chromatin, nuclear shape, the presence or absence of nucleoli, the presence and type of cytoplasmic granules, and the cytoplasmic color of stained cells (Table 6-1, page 238).

Since changes in nuclear chromatin and cell size occur during each cell replication cycle (see Chapter 2) and since the formation of granules and other cytoplasmic changes occurs gradually during the stages of cell development, morphologic definitions are necessarily arbitrary and do not always conform to significant biochemical or physiologic changes. At times it is difficult to classify a cell in one category or another since it is actually in transition between the two. Nevertheless it is useful to separate the cell lines into morphologic compartments and to define normal limits of cell distribution therein since gross changes from these patterns are indicative of disease.

### *The Myeloblast*

The term "myeloblast" describes an immature cell, normally found in the bone marrow and not in the blood. This cell can divide and give rise to promyelocytes which in turn give rise to myelocytes. It is not known whether there are separate myeloblasts for the neutrophilic, eosinophilic, and basophilic cell lines, but, if there are, no reliable criteria for identifying them exist even at the electron microscopic level.<sup>73</sup>

The myeloblast (Plate V, A and Fig. 6-1, 1 to 4) possesses a relatively large nucleus, round or slightly oval in shape, and a small amount of cytoplasm. In preparations treated with Wright's stain, the nuclear membrane is smooth and even in outline and exceedingly thin, with no condensation of chromatin near its inner surface as in lymphoblasts. The chromatin shows an even, diffuse distribution

with no aggregation into larger masses, although there may be some condensation about the nucleoli. The chromatin may appear in the form of very fine strands, thus giving the nucleus a sieve-like appearance; or it may have the form of fine dust-like granules, producing a uniform stippled effect. There are, generally, from two to five nucleoli, pale sky-blue in color. It has been claimed that a large number of nucleoli favors the myeloblast as against the lymphoblast, but this has been disputed. The cytoplasm is basophilic (blue) and generally, although not invariably, there is no clear zone about the nucleus. Sometimes the cytoplasm is reticular, spongy, or foamy.

In electron microscopic sections the above observations in general are confirmed.<sup>17</sup> The nuclear membrane is thin and indistinct with little or no chromatin condensation. The numerous particles of ribonucleoprotein in the cytoplasm produce deep-blue basophilia in stained preparations. Mitochondria are abundant but small, and the endoplasmic reticulum is flat and appears infrequently. The Golgi apparatus is indistinct and no cytoplasmic granules are present.

Some authors classify what may be slightly more mature cells with several, rather large, angular, irregular and dark-staining azurophilic cytoplasmic granules as myeloblasts. It is simpler, however, to include such forms in the promyelocyte stage thus making the separation between the two cell types clear-cut. The electron microscopic classification of myeloid cells, which is based primarily on stages of granule formation, also places cells with beginning granule formation in the promyelocyte category.<sup>13,73</sup>

In wet films, myeloblasts appear immobile, with thin, tenuous borders. The cytoplasm is hazy and usually contains no stainable substance except mitochondria, which are diffusely scattered throughout the cytoplasm and stain brilliant blue-green with Janus green. The failure of myeloblasts to move in supravitral preparations is probably due to the nature of the preparation itself rather than to the cells' immobility. In motion picture studies of hanging-drop preparations, myeloblasts

Fig. 6-1 Myeloblasts, myelocytes and lymphoblasts 1 2 3 and 4 Myeloblasts from patients with myeloblastic leukemia. In 4 there is an Auer body. 5 and 6 Promyelocytes from human marrow. 7 and 8 Very immature lymphoid cells (lymphoblasts) from a lymph node of a newly born rabbit. 9, 10 11 and 12, Lymphoblasts from patients with acute lymphoblastic leukemia (From Downey<sup>24</sup> courtesy of the author and Paul B. Hoeber.)

manifest a characteristic, snail-like movement.<sup>61</sup> The suggestion that this distinguishes them from lymphoblasts (Fig. 6-2) has been questioned, the different types of motility being ascribed to external factors.<sup>23</sup>

Since they are in the process of growth and division, myeloblasts vary considerably in size, from 10 to 20  $\mu\text{m}$  in diameter. Particularly in acute leukemia, the nucleus may show several wide and deep indentations suggesting lobulation. Such myeloblasts (see *Rieder cells*,<sup>24</sup> below) suggest a more rapid maturation on the part of the nucleus as compared

with the cytoplasm (asynchronism of DiGuglielmo).

Also in leukemia, *Auer bodies* are seen in the cytoplasm of cells which otherwise look like myeloblasts (Fig. 6-1).<sup>73</sup> Typical Auer bodies are rod-shaped cytoplasmic inclusions which stain with azure dyes and contain acid phosphatase,<sup>30</sup> peroxidase,<sup>32</sup> and esterase.<sup>35</sup> Some have considered them to be abnormal derivatives of primary granules,<sup>78</sup> and, as such, to signify beginning differentiation. However, there are differences between the fine structure of Auer rods

Fig 6-2. Diagrams (1 2 3) and photographs (4-15) of living moving unstained cells enlarged ( $\times 1000$ ) from negatives of motion picture films of tissue cultures. 1, "Worm-like" shape of myeloblast in motion. 2, Hand-mirror shape of lymphoblast in motion. 3, Shape of monocyte (histiocyte) in motion. 4 and 5, Myeloblasts from the bone marrow of a normal rabbit. 6, Myeloblast from the bone marrow of a normal person. 7 and 8, Myeloblasts from the blood of a patient with acute myeloblastic leukemia. 9, Two monocytes from normal blood. Note the broad, ruffled pseudopodia. 10, Cells from the lymph node of a three-week-old normal rabbit. There are two large, hand-mirror shaped, moving lymphoblasts (A); also note the "hand mirror" shape of moving small lymphocytes (B). 11, 12, and 13, Lymphoblasts from the blood of a patient with acute lymphoblastic leukemia. 14, Typical small lymphocytes from the blood of a patient with chronic lymphocytic leukemia. 15, Typical large lymphoid cells from the blood of a patient with infectious mononucleosis (Rich et al.<sup>41</sup> courtesy of the authors and Bulletin of Johns Hopkins Hospital.)

and primary granules.<sup>74,75</sup> Furthermore, Auer rods have been reported in monocytes, the characteristic granules of which differ substantially from those found in neutrophils.<sup>51</sup>

Rieder cells are not a specific cell type but probably represent asynchrony of nuclear and cytoplasmic differentiation in monocytes, lymphocytes, myeloblasts, leukoblasts, or reticuloendothelial monocytoïd cells; i.e., cells in which the nucleus is polymorphous or highly differentiated while the cytoplasm is immature.<sup>36</sup>

### Differentiation of Myeloblasts from Lymphoblasts and Other "Blasts"

It is extremely difficult, by present-day methods at least, to distinguish leukoblasts (myeloblasts, lymphoblasts, monoblasts) and even pronormoblasts if cells showing beginning maturational changes (granule formation or hemoglobin synthesis) are excluded from the blast category.<sup>73</sup> In the *lymphoblast* the nuclear membrane is denser than that of the myeloblast and the chromatin is coarser and may show some aggregation. These cells are contrasted in Plate XIX, A-F. There generally are only one or two nucleoli in lymphoblasts and their membrane usually is very distinct. The mitochondria are short and more plump than those of myeloblasts and often assume a position close to the nucleus. The "*monoblast*" is described as showing characteristics similar to those of the mature monocyte, such as very fine chromatin, pale nucleus, and ground-glass cytoplasm with a fine, irregular border. Additional morphologic differences will be given later in this chapter (page 234). In many instances, the identification of "blast" cells is greatly aided by the company they keep—the more mature and more easily recognized cells about them in sections, or in the same blood smear. In the case of the myeloblast, the demonstration of associated promyelocytes which show azure granulation in Wright's or similar stains, or positive reaction in the peroxidase stain, is strong presumptive evidence for this cell's identification.

### Myelocytes and Promyelocytes

The developmental stages in the granulocyte series and some of their morphologic variations are shown in Plate V, A-L, and Figure 6-3. Classically the several stages beyond the myeloblast have been differentiated primarily on the basis of the number and type of granules present, as in the A, B, and C myelocytes of Sabin<sup>64</sup> or the *promyelocyte* and differentiated *myelocyte* of Pappenheim. In these classical schemes it was generally assumed that there is an azurophilic, granule-containing cell, the progranulocyte or promyelocyte, which is a common precursor for the three granulocyte series,<sup>17</sup> and that during development these nonspecific granules degenerate and/or transform into the "specific" granules which characterize the mature neutrophil, eosinophil, or basophil. However, electron microscopic, histochemical, and biochemical evidence indicates that each granule population associated with the several stages of the myeloid series can be identified and related to a given cell line. The so-called "nonspecific, azurophilic," or *primary* granules first appear at the promyelocyte stage and can be identified on fine structural study as characteristic of the neutrophil, eosinophil, or basophil series.<sup>3,13,65,73</sup> They do not transform into "specific" granules but persist throughout the remainder of the maturation sequence and are seen in all subsequent stages including the polymorphonuclear forms<sup>10,13,65</sup> (Fig. 6-3).

The *promyelocyte* is somewhat larger on the average than the myeloblast. In both light and electron microscopic preparations it possesses a round or oval nucleus in which the nuclear chromatin is diffusely distributed, as in the myeloblast; in later stages, slight chromatin condensation is discerned around the nuclear membrane. Nucleoli are present, but as the cell develops they become less prominent. As compared with the myeloblast, the main difference, as seen with the electron microscope, is in the cytoplasm where the endoplasmic reticulum is more prominent and takes on a dilated, vesicular appearance. The azurophilic, primary granules appear and

Table 6-1 Morphologic Characteristics of the Leukocytes (Wright's Stain)

Type of Cell	Nucleus							Cytoplasm			
	Size	Position	Shape	Color	Chromatin	Nuclear Membrane	Nucleoli	Relative Amount	Color	Pen nuclear Clear Zone	Granules
1 Granulocytes											
(a) Myeloblast	10-18 $\mu$ m	Eccentric or central	Round or oval	Light reddish purple	Very fine meshwork	Very fine	2-5	Scanty	Blue	None	None
(b) Promyelocyte	12-20 $\mu$ m	Eccentric or central	Round or oval	Light reddish-purple	Very fine meshwork	Fine	2-5	Moderate	Blue	None	Azurophilic
(c) Myelocyte	12-18 $\mu$ m	Eccentric	Oval or slightly indented	Reddish-purple	Fine but becomes gradually coarser	Indistinct	Rare	Moderate	Bluish-pink	None	Azurophilic plus specific granules
(d) Metamyelocyte	10-18 $\mu$ m	Central or eccentric	Thick horseshoe or indented	Light purplish-blue	Basal and oxychromatin clearly distinguished	Present	None	Plentiful	Pink	None	Neutrophilic, eosinophilic, or basophilic
(e) "Juvenile" or band form	10-16 $\mu$ m	Central or eccentric	Band shape of uniform thickness	Light purplish-blue	Basal and oxychromatin clearly distinguished	Present	None	Plentiful	Pink	None	Neutrophilic, eosinophilic, or basophilic
(f) Polymorphonuclear neutrophil	10-15 $\mu$ m	Central or eccentric	2-5 or more distinct lobes	Deep purplish-blue	Rather coarse	Present	None	Plentiful	Faint pink	None	Fine, pink or violet pink
(g) Polymorphonuclear eosinophil	10-15 $\mu$ m	Central or eccentric	2-3 lobes	Purplish-blue	Coarse	Present	None	Plentiful	Pink	None	Large, coarse, uniform in size, crimson-red, numerous
(h) Polymorphonuclear basophil	10-15 $\mu$ m	Central	2-3 lobes	Purplish-blue	Coarse, overlaid with granules	Present	None	Plentiful	Faint pink	None	Large, coarse, uniform, bluish black

2. Lymphocytes	10-18 $\mu$ m	Eccentric or central	Round or oval	Light reddish-purple	Moderately coarse particles, "supplied"	Fairly dense	1-2	Scanty	Clear blue	Present	None
(a) Lymphoblasts											
(b) "Mature" lymphocyte	7-18 $\mu$ m	Eccentric	Round or slightly indented	Deep purplish-blue	Large masses of moderate or large size, or pyknotic	Dense	None	Scanty or plentiful	Sky-blue, deep blue, or even very pale pink	Present if cytoplasm is dark	None or few, azurophilic
3 Monocyte	12-20 $\mu$ m	Eccentric or central	Round, oval, notched or horseshoe	Pale bluish-violet	Fine reticulated, skein-like or lacy	Present	None	Abundant	Grayish or cloudy blue	None	Abundant, fine, lilac or reddish blue
Macrophage	15-80 $\mu$ m	Central	Elongated, indented or oval	Pale bluish-violet	Spongy	Distinct	None	Usually abundant	Opaque sky-blue	None	Numerous, moderately coarse azure granules and vacuoles

Fig 6-3. Diagrammatic representation of the appearance of granules during neutrophil maturation. Myeloblasts are relatively undifferentiated cells with a large oval nucleus, large nucleoli, and cytoplasm lacking granules. They originate from a precursor pool of stem cells. Subsequently, there are two secretory stages—the promyelocyla and the myelocyla—each of which produces a distinct type of secretory granule, azurophilic (dark granules) are produced only during the promyelocyla stage, specific granules (light granules) are produced during the myelocyla stage. The metamyelocyla and band forms are nonproliferating, nonsecretory stages that develop into the mature PMN characterized by a multilobulated nucleus and cytoplasm containing primarily glycogen and granules. Both nonspecific azurophilic granules and specific granules persist throughout these later stages. (Modified from Bainton et al.<sup>13</sup> courtesy of the author and the Journal of Experimental Medicine)

Fig 6-4. Early and late promyelocytes, a myelocyte, and a polymorphonuclear neutrophil viewed by electron microscopy (Courtesy D Bainton, University of California, San Francisco)

**A. Early neutrophilic promyelocyte** (reacted for peroxidase,  $\times 10,500$ ). The nucleus (N) with its prominent nucleolus (Nu) occupies the bulk of this very immature cell. The surrounding cytoplasm contains a few azurophilic granules (ag), a large Golgi complex (G), Golgi cisternae (Gc), several mitochondria (m), scanty rough endoplasmic reticulum (er), and many free polysomes (r). A centriole (cc) is present in the Golgi region.

All of the azurophilic granules (ag) appear dense, since they are strongly reactive for peroxidase. The secretory apparatus (ie, the perinuclear cisterna [pn], rough endoplasmic reticulum [er], and Golgi cisternae [Gc]) are also reactive, although less so than the granules.

Specimen fixed in glutaraldehyde for 16 hours at  $4^{\circ}\text{C}$ , incubated in the peroxidase medium of Graham and Karnovsky for one hour at  $22^{\circ}\text{C}$ , post fixed in  $\text{OsO}_4$ , treated in block with uranyl acetate, dehydrated in ethanol, infiltrated with propylene oxide, and embedded in Araldite. Section stained for one minute with lead citrate.

**B. Late neutrophilic promyelocyte** (reacted for peroxidase,  $\times 7,000$ ). This cell is the largest ( $\sim 15 \mu\text{m}$ ) of the neutrophilic series. It has a sizable, slightly indented nucleus (N), a prominent Golgi region (G) and cytoplasm packed with peroxidase-positive azurophilic granules (ag). Note the two general shapes of the azurophilic granules, spherical (ag) and ellipsoid (ag'). The majority are spherical, with a homogeneous matrix, but a few ellipsoid forms containing crystalloids also are present. Many of the spherical forms (ag) have a dense periphery and a lighter core, owing presumably to incomplete penetration of substrate into the compact centers of mature granules.

Peroxidase reaction product is visible (under higher magnification) in less concentrated form within all compartments of the secretory apparatus (endoplasmic reticulum, perinuclear cisterna, and Golgi cisternae). No reaction product is seen in the cytoplasmic matrix, mitochondria, or nucleus.

Specimen fixed in glutaraldehyde for 10 minutes at  $4^{\circ}\text{C}$  and subsequently processed exactly as was specimen A.

Fig. 6-4. (continued from page 23D)

C. *Neutrophilic myelocyte* (reacted for peroxidase  $\times 9\ 000$ ) At this stage the cell is smaller ( $\sim 10\ \mu\text{m}$ ) than the promyelocyte, the nucleus is more indented, and the cytoplasm contains two different types of granules: (1) large, peroxidase-positive azurophilic (ag) and (2) the generally smaller specific granules (sg), which do not stain for peroxidase. A number of immature specific granules (is), which are larger, less compact, and more irregular in contour than mature granules, are seen in the Golgi region (G). Note that peroxidase reaction product is present only in azurophilic granules, and is not seen in the rough endoplasmic reticulum (er), perinuclear cisterna (pn), and Golgi cisternae (Gc). This is in keeping with the fact that azurophil production has ceased and only peroxidase-negative specific granules are produced during the myelocyte stage.

D. *Mature PMN* (reacted for peroxidase,  $\times 10\ 500$ ) The cytoplasm is filled with granules, the smaller peroxidase-negative specific granules (sg) are more numerous, the azurophilic (ag) having been reduced in number by cell divisions after the promyelocyte stage. Some small, irregularly shaped azurophilic granule variants are also present (unlabeled arrow). The nucleus is condensed and lobulated ( $N^1-N^4$ ). The Golgi region (G) is small and lacks forming granules, the endoplasmic reticulum (er) is scanty, and mitochondria (m) are few. Note that the cytoplasm of this cell has a rather ragged, moth-eaten appearance due to the fact that the glycogen, which is normally present, has been extracted in this preparation by staining in block with uranyl acetate.

accumulate in increasing numbers during this stage, but the so-called specific or secondary granules are not yet present<sup>3,10,13,17,73</sup> (Fig. 6-4). In early promyelocytes the few granules present may be difficult to see by light microscopy as they often lie over the nucleus and are evident only on examination at several focal planes.

Like the myeloblast, the promyelocyte is immobile in flat slide and coverslip preparations and only in the last stage is slight locomotion seen. Even then the streaming of granules so characteristic of mature granulocytes is lacking.<sup>4</sup> For this reason the cytoplasm has been thought to be in the form of a gel; the increased resistance of the cytoplasm of immature myeloid cells to changes in shape has been proposed as a factor in retention of these cells in the bone marrow.<sup>16,17</sup> In hanging-drop preparations, promyelocytes are actively mobile, however.

The *neutrophilic myelocyte* may be defined as the stage in which *specific (secondary) granules* appear in the cytoplasm and the cell consequently can be identified as belonging to the neutrophilic series when stained and observed with the light microscope. As mentioned above, earlier identification of a cell that will become neutrophilic can be made by electron microscopic examination of the primary, "nonspecific" granules. The nucleus of the neutrophilic myelocyte usually is eccentric, round or oval in shape, and one side may appear somewhat flattened. The nuclear chromatin is somewhat coarse, and nucleoli are small and often not visible, although they are clearly seen with the electron microscope.<sup>3</sup> Primary granules persist in myelocytes, but formation of new primary granules stops abruptly, and each succeeding cell division leads to a decrease in their number (Fig. 6-3) in the daughter population.<sup>4,10,13</sup> The secondary granules of the neutrophil series are smaller than the primary granules and in the rabbit, cat, and man are formed in increasing numbers on the convex surface and lateral borders of the somewhat less prominent Golgi apparatus.<sup>3,10,13</sup> The amount of granular endoplasmic reticulum is reduced in the myelocyte as compared to earlier forms,

and thus the cytoplasmic basophilia decreases and disappears. The mitochondria remain small and relatively few in number.

### *Nature of Primary and Secondary ("Specific") Granules*

It has been suggested, from studies in the rabbit and cat, that the primary granules are packaged and released from the inner, concave surface of the Golgi apparatus (Fig. 6-5A) in contrast to the secondary (so-called "specific") granules of the myelocyte and later granulocyte stages which appear to be formed and released from the outer, convex surface.<sup>3,10,13,65</sup> Recently this also has been shown to be the case in man.<sup>13</sup> Some workers, however, believe that the primary granules are formed diffusely throughout the cytoplasm by the condensation of precursor vacuoles without the Golgi apparatus being involved in their formation.<sup>65</sup> In the mature neutrophil, a ratio of secondary to primary granules of about 9 to 1 is seen in the rabbit<sup>73</sup> and 2 to 1 in man.<sup>13</sup>

The mature *primary granules of human neutrophils* usually contain central crystalloids when lightly stained.<sup>65</sup> They apparently bind neutral red dye and thus are easily seen as neutral red bodies in supravital preparations.<sup>2</sup> They are membrane-bound lysosomes which contain a number of enzymes and other substances, such as acid phosphatase, peroxidase, esterase,  $\beta$ -glucuronidase,  $\beta$ -galactosidase, aryl-sulfatase, 5'-nucleosidase, N-acetyl- $\beta$ -glucosaminidase,  $\alpha$ -mannosidase, sulfated mucosubstance, lysozyme and other basic proteins.<sup>13,73</sup> There is considerable variation in *acid phosphatase* activity as reported in different studies and in different species.<sup>3,10,11</sup> This may be due to inadequacies of the histochemical assays or perhaps is related to species variations.<sup>73</sup> *Peroxidase* has been associated with primary granules by histochemical, cytochemical, and biochemical methods and at the present time is the best marker for primary granules in mammals.<sup>73</sup> *Sulfated mucosubstance* presumably accounts for the azurophilic staining of the primary granules; the uptake of radiosulfate by early

Fig 6-5. Granule formation in neutrophil precursors viewed by electron microscopy (Courtesy D. Bainton, University of California, San Francisco)

A. Golgi region of a neutrophilic promyelocyte reacted for peroxidase ( $\times 40,000$ ). At this stage the peroxidase reaction product is present within the rough endoplasmic reticulum (er), the clusters of smooth vesicles (vel) located at the periphery of the Golgi cisternae (Gc) in the Golgi cisternae, and in the immature (ia) and mature (ag) azurophilic granules. The immature granules are larger and less compact than the uniformly dense mature granules.

B. Golgi region of a neutrophilic myelocyte reacted for peroxidase ( $\times 40,000$ ). Peroxidase reactive material is seen in the primary or azurophilic granules (sg) but not in the specific (secondary) granules (ag). At this stage (myelocyte) no peroxidase reaction product is seen in the endoplasmic reticulum, Golgi cisternae (Gc) or newly formed immature specific granules (is). The stacked Golgi cisternae are oriented around the centriole (ce) and the outer cisternae (unlabeled arrow) contain material of intermediate density that is similar to the content of the specific granules, suggesting that the specific granules arise from the convex face of the Golgi complex as in the rabbit.

neutrophils<sup>43,70</sup> may be due to incorporation into this substance. About *one third* of neutrophil *lysozyme* appears to be present in the primary granules of rabbit neutrophils<sup>9</sup> and several other bactericidal, basic proteins have been localized in the primary granule fraction as well.<sup>79</sup> A number of *acid hydrolases* such as  $\beta$ -glucuronidase have been found in mixed granule fractions. *Alkaline phosphatase* appears to be absent from the primary granules of rabbits and man.<sup>11,13,73</sup>

The *secondary* granules of the neutrophil are characterized by their content of alkaline phosphatase and lack of acid phosphatase<sup>13,73,79</sup>; they also lack or contain very little peroxidase and sulfated mucosaccharide.<sup>73</sup> In addition, secondary granules contain amino peptidase, lysozyme, collagenase, and basic proteins. *Alkaline phosphatase* has been found in blood and exudate neutrophils by many workers, but considerable variation is seen between species<sup>3,11,73</sup> and in pathologic states.<sup>38</sup> Histochemical<sup>11,13,73,75</sup> and biochemical studies<sup>9,79</sup> indicate that this enzyme is located in the secondary granules of the granulocytes in man and in rabbits. *Lysozyme* has been identified in human neutrophil secondary granules<sup>31</sup> as well as in primary granules; about two thirds of this antibacterial basic protein is in the secondary granule.<sup>9,79</sup> *Aminopeptidase* appears relatively late in myelocyte maturation,<sup>2</sup> and *collagenase* has been reported in human blood granulocytes.<sup>41</sup> A variety of basic proteins also has been reported in cytoplasmic fractions in which the secondary granules predominate.<sup>73</sup>

A third form or *tertiary granule* has been described in human neutrophils,<sup>65,71</sup> but some investigators regard this as merely a morphologic variation of primary and secondary granules.<sup>13</sup> The "tertiary" granules first appear during the late myelocyte stage and are described in late marrow and blood forms. Whether these granules are formed beyond the myelocyte stage is unknown, but this has been thought to be likely.<sup>65</sup>

### *Metamyelocytes*

The metamyelocyte is characterized by a clearly indented or horseshoe-shaped nucleus

(Plate V, B, H, I) without nucleoli (even by EM examination) and the nuclear chromatin is moderately dense with considerable clumping evident along the nuclear membrane. The cytoplasm is filled with both primary and secondary (and, in man, perhaps tertiary<sup>65</sup>) granules, but the secondary granules predominate. The endoplasmic reticulum is sparse as are polysomes, thus signifying the virtual completion of protein synthesis.

The boundary between the myelocyte and metamyelocyte compartments is best defined physiologically by the fact that myelocytes synthesize DNA, take up tritiated thymidine into their nuclear chromatin, divide, and are actively involved in protein synthesis as evidenced by the presence of nucleoli, abundant endoplasmic reticulum, and polysomes. Before modern techniques became available, differentiation between myelocytes and metamyelocytes was defined mainly in terms of nuclear shape. This now is recognized as a poor criterion since it has been shown in time-lapse microcinematographic studies of human neutrophils that myelocyte nuclei may assume a markedly indented shape and may subsequently revert to an oval configuration and enter mitosis.<sup>14</sup> Consequently, in classifying cells at this stage, particular attention should be paid to evidence in the nucleus and cytoplasm that protein synthesis has decreased or stopped. This is judged by the fact that the nuclear chromatin is coarse and clumped and by the faint pink of the cytoplasm which in stained preparations is essentially the color of the mature cell. These features also are helpful in differentiating metamyelocytes (Plate V, H, 7) from monocytes (Plates V, Q, R and VI, 22-25) since, in the latter, nuclear chromatin remains fine and evidence of protein synthesis persists. Amoeboid movement is apparent in metamyelocytes, even in coverslip slide preparations.

### *"Juvenile" or "Band" Forms* (Plate V, J, K)

This stage is characterized by further condensation of nuclear chromatin and transformation of nuclear shapes into sausage or band configurations which possess approxi-

mately uniform diameters throughout their length (Fig. 6-3). Subsequently one or more constrictions begin to develop and progress until the nucleus is divided into two or more lobes connected by filamentous strands of heterochromatin, the polymorphonuclear stage. There has been considerable difference of opinion concerning the differentiation of the juvenile (band) and polymorphonuclear stages. Some workers require a clearly visible filamentous strand between lobes (Plate V, N) before classifying a cell as a polymorphonuclear form; anything less clear-cut, whether due to overlapping of nuclear lobes or to incomplete constriction, is classified as a band form.<sup>55,60</sup> Others regard a constriction greater than one half or two thirds of the nuclear breadth (Plate V, L) as adequate evidence of lobulation and classify such cells as polymorphonuclear,<sup>18,26</sup> or use other slightly different criteria.<sup>58</sup> Still others avoid the issue entirely. Unfortunately, no clear agreement has been reached. Since, as far as is known, there is no clear difference between band and segmented stages other than nuclear shape and a slightly earlier appearance of tritiated thymidine in the band forms, the distinction becomes an arbitrary one. Nevertheless, a clear and easily recognizable separation is needed if one wishes to count nuclear lobes for diagnostic purposes, as in the early detection of folic acid deficiency<sup>33</sup> or in assessing marrow release of young forms into the blood.<sup>50</sup> For such purposes we have chosen as the criterion for inclusion in the polymorphonuclear category the clear separation of nuclear lobes.<sup>55</sup> Cells without this complete formation of distinct lobes are classified as band forms.

#### *Polymorphonuclear Neutrophils* (Plate V, L, M, N)

In this stage of full maturity the cells usually are of essentially uniform size and granule content. In Wright-stained preparations the nucleus is found to take a deep, purplish color and contains coarse, condensed chromatin. The lobes are joined by thin filaments of chromatin although these may not be easily visible if the lobes are partially super-

imposed on one another. Careful examination by focusing through several planes may facilitate identification. The cytoplasm is faint pink and contains fine, specific granules which sometimes may give only a ground-glass appearance. The azurophilic, primary granules have usually lost their dark-staining characteristics by this stage, but can be seen with the electron microscope. Under the electron microscope the granules exhibit considerable variation in density, presumably a reflection of variation in enzyme content, and they maintain a minimum distance of 100 nm from the cell membrane.<sup>81</sup> Large masses of glycogen become evident for the first time in mature neutrophils; this may reflect their propensity for anaerobic metabolism. The purpose of nuclear lobulation is not known. Perhaps it enhances cell deformability and movement through vessel walls and into sites of inflammation, or perhaps nuclear segmentation results from nucleolar emptying and has no function.<sup>274</sup> Arneth believed that nuclear lobulation continues as the cell ages and that granulocytes with three or four lobes are more mature than those with only two.<sup>5</sup> This may be true in the sense that once nuclear constriction begins the completion of lobulation may continue for some time; during this interval the cell may be delivered to the blood and thus completion of lobulation may occur in the blood (or in cultures). However, the number of lobes a neutrophil will develop appears to be determined in the band stage (or earlier), and the time of appearance of neutrophils in the blood after pulse labeling with tritiated thymidine was found to be unrelated to the number of nuclear lobes.<sup>211</sup>

In wet films, marked amoeboid activity of polymorphonuclear neutrophils at physiologic temperatures is characteristic. First, long pseudopods of granule-free ectoplasm are extended and into this the endoplasm with its dancing granules advances. The cell moves in this fashion, generally, but erratically, in one direction for a considerable period of time. The nucleus follows passively and may be elongated or compressed into bizarre shapes. Often, as the cell proceeds, a loop strand of cytoplasm remains stretched out behind it. Finally this is drawn up or occa-

sionally it may be broken off. The rate of neutrophil locomotion has been estimated at 19  $\mu\text{m}$  per minute.<sup>45</sup> In supravitaly stained films the (specific) granules appear yellowish pink and are refractile; in addition, occasional larger, nonrefractile deep-red vacuoles may be seen.

"Senile" polymorphonuclear leukocytes that are no longer motile and fail to take up the neutral red stain have been described in *in vitro* preparations.<sup>64</sup> They are seen in small numbers in the blood where their survival time is short.<sup>212</sup>

### *Eosinophils* (Plate V, O)

Eosinophils exhibit the same maturation phenomena as neutrophils except that probably only one type of granule is formed.<sup>73</sup> In rabbits the earliest identifiable eosinophils have fine nuclear chromatin and well-developed nucleoli, and contain large mitochondria, dilated endoplasmic reticulum, and a few large, dense, homogenous granules. These homogenous granules appear to be formed throughout all the subsequent stages of maturation. Their contents are first seen as flocculent material in Golgi saccules, then in small vacuoles which condense to form the large homogenous, dense granules. Subsequently, crystalloids develop and the granules acquire an angular shape; the angular configuration predominates in the mature polymorphonuclear forms and is also seen in human eosinophils.<sup>71</sup> Condensation in nuclear chromatin, decrease in size and ultimate disappearance of nucleoli, and reduction in the size of the Golgi apparatus parallel the changes seen during neutrophil maturation (Fig. 6-3). It is unusual to find more than two lobes in mature eosinophils and the lobes are larger than those seen in neutrophils. Eosinophilic granules are considerably larger than neutrophilic granules, appear somewhat refractile under the light microscope, and stain a bright yellowish red with Wright's stain.<sup>4</sup> Eosinophils are less actively motile than are neutrophils.

Cytochemically, eosinophilic granules (both homogenous and crystalline) are composed of a zinc-containing basic protein and peroxidase, but lack alkaline phosphatase, lysozyme, and bactericidal proteins. In addition, a number of other components have been identified in the granules: PAS reactive mucosubstance, acid phosphatase, ribonuclease,  $\beta$ -glucuronidase, cathepsin, aryl sulfatase, deoxyribonuclease, nucleotidase, lipase, and plasminogen.<sup>73</sup> Of the mature granulocytes, eosinophils display the most intense staining with peroxidase; the intense eosinophilic staining appears to be due to their basic protein content.

### *Basophils and "Mast" Cells* (Plate V, P)

Basophils are distinguished by their large, coarse, purplish-black granules (Plate V, P) that usually fill the cytoplasm and often obscure the nucleus. The granules are water soluble and thus may be dissolved in the process of staining and washing; the cells may then appear vacuolated with only a few or no basophilic granules remaining. On electron microscopic examination there is similar variation in the appearance of the basophilic granules. This is thought to reflect variable extraction of granule contents during preparative procedures rather than sequential production of several granule types as in the neutrophil.<sup>73,80</sup> In segmented basophils, mitochondria are large and numerous as in the eosinophil. In contrast to neutrophils, glycogen is much less abundant.<sup>71</sup>

Basophils exhibit sluggish motility; the nucleus advances rather than the cytoplasm as in the neutrophil and eosinophil.<sup>4</sup> The granules contain large amounts of heparin and histamine<sup>2,81</sup> (sulfated acid mucosubstance) and this is probably responsible for the affinity of the granules for basic dyes. Aryl sulfatase probably also is present, but peroxidase and alkaline and acid phosphatase are not.<sup>73</sup>

Similar but somewhat larger cells are found in the tissues and are known as *mast*

# PLATE VI

*Monocytes from the blood of a patient who died of miliary tuberculosis. Similar cells were seen in the tissues about the tuberculous nodules.*

11, Typical monocyte, 1, 2, and 6 have nuclei which are a little darker and are somewhat more stippled than is usual but are otherwise typical monocytes.

13, Small monocyte.

9, Most probably is a monocyte even though the nucleus is somewhat less distinct than in the other cells.

12, Polymorphonuclear leukocyte showing "toxic" granulation.

cells. Although these cells resemble basophils in their metachromasia, acid nature, and content of histamine and heparin, they contain hydrolytic enzymes and 5-hydroxytryptamine<sup>1</sup> which basophils do not.<sup>12</sup> Also the ultrastructure of their granules is different in both man and the guinea pig.<sup>12</sup> Mast cells appear to discharge their granules outside the cell ("exoplasmosis"), while basophils usually undergo diffuse internal degranulation after phagocytosis although they may also exhibit exoplasmosis.<sup>81</sup>

### *Macropolycytes*

Macropolycyte is the name applied to giant polymorphonuclear neutrophils with a diameter greater than 16  $\mu\text{m}$  (as compared to normal mean 10 to 12  $\mu\text{m}$ , upper limits 15  $\mu\text{m}$ <sup>58</sup>) and possess from 6 to 14 nuclear lobes.<sup>39</sup> Such cells are seen only very occasionally in healthy subjects (1.3%), but they are found in about 5% of subjects with infections of various types or with intoxications, usually in association with a neutrophilic leukocytosis and the presence of myelocytes in the blood.<sup>39</sup> Macropolycytes are most commonly seen in association with folic acid or vitamin B<sub>12</sub> deficiency. We have often seen them also in patients recovering from the pancytopenia that attends treatment with cytotoxic agents.

Some authors have described cells with hypersegmented nuclei but of a normal size and refer to them as polycytes<sup>60</sup> or polylobocytes<sup>58</sup>; similar cells with complex nuclei but without hypersegmentation are called polypolycytes.<sup>60</sup> The latter forms are seen in perhaps 10% of patients recovering from leukocytosis with a marked shift to the left (see page 242) and appear in increasing numbers when anticoagulated blood is allowed to stand *in vitro*.<sup>56,60</sup>

The mechanism of macropolycyte formation is unknown, but it has been suggested that the skipping of one of the usual cell divisions that occurs during maturation results in a hypersegmented cell.<sup>72</sup>

### *Genetic Sex as Indicated by Leukocytes*

Only one X chromosome is essential to the normal activity of a cell; the other in the normal XX female remains unextended and thus is visible as a chromatin body. Sex chromatin (Barr) bodies are present in 80 to 90% of the somatic cells of the normal female. The sex chromatin body of the neutrophil of females is a small mass, usually adjacent to the nuclear membrane which stains deeply with hematoxylin, Feulgen reagent, and thionin and is about 0.7 to 1.2  $\mu\text{m}$  in size. It takes the form of a "drumstick" projecting from one of the nuclear lobes of about 2 to 3% (extreme range 1 to 17%) of the segmented neutrophils in the blood.<sup>21</sup> The "drumsticks" are well-defined, solid, round projections of chromatin connected to a lobe by a single fine chromatin strand (Fig. 6-6). They must be distinguished from "small clubbed" or racket-structured, nonspecific nodules which may be of smaller or larger size and are irregular in shape or lacking in chromatin, as well as from small (minor) lobes attached to the rest of the nucleus by two strands. Sessile nodules are equally sex specific but are more difficult to recognize.<sup>49</sup> Drumsticks are not found in normal males.<sup>21</sup>

It has been claimed that a sex chromatin body can also be identified in lymphocytes, monocytes, and nonsegmented neutrophils as a planoconvex or elliptical mass of dark-staining chromatin closely applied to the inner aspect of the nuclear membrane, but there is some doubt that this represents true sexual chromatin.<sup>52,53</sup>

The number of chromatin bodies seen in a cell is one less than the number of X chromosomes present. With the increased numbers of X chromosomes found in certain disorders of human development the number of Barr bodies and drumsticks increases and isochromosomes formed by duplication of the long arms of the X chromosome give rise to larger drumsticks than are found in the normal female.<sup>20</sup> Drumsticks or sessile nodules are seen in chromatin-positive males

Fig 6-6. Granulocytes, to show the sex chromatin. The characteristic drumsticks found in the female are shown in the two cells on the left, the thin strand of chromatin joining the head to a nuclear lobe can be seen clearly. In the two cells on the right "small clubs" are present such as may be seen in males. These should not be confused with drumsticks. (Wright's stain  $\times 1300$ .)

with Klinefelter's syndrome and are absent in chromatin-negative females with Turner's syndrome. Eosinophils and probably basophils also possess drumsticks. Drumsticks may be difficult to find in the presence of a marked shift to the left. Drumstick counts have been reported to be low in the leukocytes of patients with chronic myelocytic leukemia, paralleling the low leukocyte alkaline phosphatase and catalase concentrations.<sup>67</sup>

Double drumsticks<sup>49</sup> or a sessile nodule plus a drumstick in the same neutrophil is very rare.<sup>22</sup> Chromosomal abnormalities have been described in the leukocytes of  $D_1$  (13-15)-trisomy<sup>33</sup> and in mongolism (Down's syndrome).<sup>40</sup> Chromosome duplication has been studied in cultured human leukocytes.<sup>8</sup>

### The Monocyte Series

The monocyte is a phagocytic leukocyte found in the blood of vertebrates. So named by Pappenheim and Ferrata<sup>118</sup> the monocyte was first clearly differentiated by Schilling in 1912. It had been referred to as a "transitional cell" by Ehrlich because he thought it represented a transitional stage between immature mononuclear cells and the neutrophilic leukocyte.

Sabin and coworkers<sup>98</sup> regarded these cells as derived from a specific stem cell, the *monoblast*. The monoblast was described as being nonmotile, about  $14\ \mu\text{m}$  or greater in diameter, and characterized by basophilic or grayish cytoplasm, a large nucleus with little indentation, fine, stringy chromatin and one

or two large nucleoli. Numerous fine, spherical or slender, rod-like mitochondria appear in supravital stained cells, but neutral red vacuoles are absent or only a very few fine bodies are seen. These are presumably pinocytotic vesicles. On electron microscopic examination, aggregated ribosomes and scattered strips of endoplasmic reticulum can be seen in the cytoplasm, but the Golgi apparatus is small.<sup>105</sup> Differentiation of the monoblast from the myeloblast is difficult and probably impossible, even at the electron microscopic level.

### Promonocytes

The promonocyte or young monocyte is up to  $20\ \mu\text{m}$  in diameter and possesses a large, moderately indented nucleus. A nucleolus may be visible on light microscopy. The cell is motile and phagocytic but less so than the mature monocyte.<sup>110</sup> The cytoplasm shows considerable basophilia. No azurophilic granules are seen on light microscopy, but a few fine neutral red bodies may be distinguished. The cytoplasmic border often exhibits uneven extensions, or ruffled pseudopods. On electron microscopy, endoplasmic reticulum and ribosomes are evident and the Golgi apparatus is well developed with beginning cytoplasmic granule formation.<sup>113</sup>

### Monocytes (Plates V, Q, R, VI)

The mature monocyte is easily distinguished from other cells of the blood in well-stained preparations. It is usually larger

than other leukocytes (16 to 20  $\mu\text{m}$ ) and possess a large, oval or somewhat indented nucleus. The nuclear chromatin is delicate and the membrane is thin. The nucleus usually is centrally placed and one or two small nucleoli may rarely be present. The cytoplasm is abundant, grayish or muddy blue in color (Wright's stain), and is filled with myriads of fine lilac or reddish-blue vacuoles (Plate VI). If the preparation is not over-stained, the granules resemble fine dust or give the bluish cytoplasm a ground-glass appearance; if the stain is heavy, the granules appear more prominent and the cell may be confused with a metamyelocyte or even a band form of neutrophil. The very delicate chromatin and the bluish color of the cytoplasm in the monocyte are most helpful in differentiation. Granules in monocytes are stained by the peroxidase method but are fewer and finer than those in granulocytes.

In *supravital* stained films, numerous (40 to 80) neutral red bodies, varying in size from minute, dust-like granules to rather large vacuoles, are seen, often congregated near the nuclear hof. In some species (rabbit and guinea pig) these form a "rosette," but in man this arrangement is not usual.<sup>4,109</sup> Many spherical mitochondria can be seen scattered throughout the cytoplasm in preparations stained with Janus green.<sup>4</sup> The motility of the monocyte is characteristic in that large, filmy, irregular pseudopods extend slowly from the delicate cytoplasm and the cell advances in a sliding fashion with constant fluttering and waving of these projections (Fig. 6-2). On *electron microscopic examination* the mature monocyte contains a horseshoe-shaped nucleus, with dense, granular peripheral chromatin surrounding an extensive, light-staining central nucleoplasm. Nucleoli have been observed in as many as 50% of blood monocytes.<sup>113</sup> The mitochondria are round or elongated and are usually located in the periphery of the abundant cytoplasm. The Golgi apparatus is well developed and small vesicles are especially numerous in this region but may be found throughout the cytoplasm. On morphologic grounds these vesicles appear to be of several types.<sup>110,113</sup> In

addition, oval or rod-shaped dense bodies are seen in the perinuclear region and filaments have been described in the perinuclear and centriole regions<sup>110</sup> and throughout the cytoplasm.<sup>113</sup>

#### *Macrophage, Clasmatocyte, or Histiocyte*

Whether these cell forms are closely related or of very different origins was at one time debated.<sup>98,124</sup> Metchnikoff used the term "macrophage" (as opposed to microphage) to refer to all the mononuclear phagocytes found in tissues. Aschoff used the term "histiocyte" to include both *monocytes* and *clasmatocytes* which he regarded as identical. Sabin, on the other hand, although initially agreeing with this concept, subsequently concluded that there are two types of wandering phagocytes, the clasmatocyte and the monocyte. She regarded the Kupffer cells as anchored endothelial phagocytes with the same endothelial origin as the clasmatocyte; she believed that the monocyte was of different origin.

In 1939 Ebert and Florey showed that inflammatory macrophages are derived from blood monocytes,<sup>102</sup> supporting a view previously held by many workers.<sup>122</sup> Others argued that mononuclear phagocytes are derived from lymphocytes or from the reticulo-endothelial system.<sup>103,121</sup> In more recent studies in which allogeneic bone marrow cells or tritiated-thymidine-labeled syngeneic marrow cells were transfused into irradiated recipients,<sup>92,108,133</sup> the myelogenous origin of mononuclear phagocytes was clearly demonstrated (see page 267). Studies in splenectomized animals ruled out the spleen as a major source of macrophages.<sup>130</sup> In addition, lymphocytes isolated from blood did not become macrophages in cultures while monocytes did.<sup>119,129</sup> These findings and the time of appearance of tritiated thymidine in blood monocytes and peritoneal macrophages appear to have established the marrow as the source of blood monocytes and these cells in turn as the major source of macrophages in sites of inflammation (see page 267).<sup>129</sup>

The *macrophage* is a large, actively phagocytic cell (15 to 80  $\mu\text{m}$  in diameter) with an irregular shape. Its motility is similar to that of the monocyte. Macrophages having bleb-like and filiform pseudopodia are commonly seen. The cytoplasm is abundant and has many neutral red bodies scattered throughout it.<sup>90</sup> The nucleus is egg-shaped or may be indented or elongated. When stained with Wright's stain the chromatin appears "spongy" and the nuclear membrane is distinct. The cytoplasm is sky-blue and contains many coarse, azure granules and vacuoles. Electron microscopy of mouse peritoneal macrophages has demonstrated a spectrum of cell types ranging from a few small cells resembling blood monocytes to large ones with extensive cytoplasm, Golgi apparatus, and lysosomal granules.<sup>110</sup> A similar sequence of changes can be observed as human monocytes differentiate in tissue culture into macrophages, and subsequently into epithelioid cells and giant cells.<sup>107,122</sup>

The differentiation and maturation of mononuclear phagocytes have been studied under in vitro and in vivo conditions and the morphologic and biochemical events have been described in some detail.<sup>90,95,110</sup> In general, there is considerable variation depending on the site from which the macrophages are derived (peritoneum, pulmonary alveoli, sites of inflammation) and their prior exposure to conditions that induce or accelerate formation of hydrolytic enzymes and other manifestations of differentiation.<sup>90</sup> These morphologic variations presumably account for the different designations, such as clasmatocyte and histiocyte, used in earlier literature.<sup>98,99</sup>

### *Epithelioid Cells and Giant Cells*

Monocytes transform into macrophages which in turn may develop the characteristics of epithelioid cells, and then may ultimately fuse to form multinucleated giant cells. These changes have been followed in cultures of blood monocytes from humans<sup>107</sup> and other animals<sup>122,127</sup> and in inflammatory lesions such as experimental tuberculosis in rab-

bbits.<sup>100,125</sup> The epithelioid cell is larger than the monocyte and possesses an indented or oval nucleus with heavy chromatin. The cytoplasm is abundant and contains a great many vacuoles, a few mitochondria, and cytoplasmic filaments. The cell is highly phagocytic and intense protein synthesis is evident. It has been claimed that several types of giant cells are formed either by fusion of epithelioid cells or by amitotic division of monocytes,<sup>125</sup> but it seems likely that these several forms reflect minor variations of the same process. In giant cells, multiple Golgi regions are seen, mitochondria become prominent, and cytoplasmic filaments are quite numerous, whereas lysosomes become less prominent or absent, perhaps as a result of a change in function from one of phagocytosis and particle removal to one of active transport.<sup>127</sup>

*Lymphocytes* and plasma cells are described in Chapter 7.

The *morphologic characteristics of the various leukocytes* are summarized in Tables 6-1 and 6-2. Nucleated forms of the erythrocyte series are easily distinguished from most of the leukocytes by their lack of cytoplasmic granules. In Romanowsky-stained films, confusion arises only in the very immature (blast) stage. Even then the more granular and clumped nuclear chromatin may help to identify the pronormoblasts. Polychromatophilic normoblasts at times may be confused with plasma cells or lymphocytes. In the polychromatophilic normoblast the nucleus is more centrally placed than that of the plasma cell or lymphocyte, the cytoplasm is blue-pink in color, and the cell border may be irregular. The mature lymphocyte is characterized by coarse, clumped chromatin in a nucleus which is eccentrically placed in sparse cytoplasm; a few granules may be present also (Fig. 7-1). Deep blue cytoplasm in a cell with an eccentric nucleus containing very coarse, clumped chromatin is the hallmark of the plasma cell (Chapter 7).

The nucleated cells of the red cell series are nonmotile and in wet films have a rounded, distinct border with homogeneous, nongranular yellowish cytoplasm. The nucleus is round or oval and centrally placed.

The chromatin arrangement gives the nucleus a vesicular appearance and in early forms one or two large nucleoli are present. In supravitality stained preparations no neutral red bodies are seen, but many coarse, rod-shaped and coccoid mitochondria are found scattered diffusely in the cytoplasm.

The student will find it valuable, when learning to identify the various cells of the blood, to systematically seek each of the morphologic criteria listed in Tables 6-1 and 6-2. By doing so he will acquire the habit of seeing all that he is looking at, and in time he will learn to identify cells because of a number of characteristics which he perceives unconsciously. The actual identification of cells regarding which there may be some doubt can be made only by weighing the evidence for and against each type being considered. It must be kept in mind that practically no character of a cell is entirely specific. Thus, a perinuclear clear zone is sometimes seen in cells other than lymphocytes and a rosette of neutral red bodies has been observed in many types of blood and connective tissue cells other than monocytes.

### Differential Cell Counting

Differential cell counting refers to the enumeration and classification of the leukocytes seen on the blood smear. The usual procedure is to count at least 100 leukocytes while systematically scanning the smear in an area of good cell distribution. A uniformly thin smear of blood on a coverslip is the most satisfactory preparation for such examination (see Chapter 1, page 24). Smears drawn or pulled on slides are less suitable because the smear tends to be thicker and the larger leukocytes accumulate at the edges while the smaller ones, usually lymphocytes, become concentrated in the central portions of the film.<sup>154</sup> Ideally all the leukocytes on both coverslips should be counted and classified thus identifying all the cells in a single drop of blood. Since this is impractical a representative sample is examined. An area of good cell distribution (Chapter 1, page 27) is selected under low-power magnification

**Table 6-3. The 95% Confidence Limits for Differential Leukocyte Counts**

Percentage of Given Cell Type	100 Cells Counted	200 Cells Counted
0	0.0- 3.0	0.0- 1.5
1	0.5- 4.7	0.2- 3.1
2	0.4- 6.3	0.7- 4.6
3	0.8- 7.7	1.3- 5.9
4	1.4- 9.1	2.0- 7.2
5	2.0-10.5	2.7- 8.5
10	4.0-16.0	5.8-14.2
20	12.0-28.0	14.3-25.7
30	20.8-39.2	23.5-36.5
40	30.2-49.8	33.1-46.9
50	40.0-60.0	42.9-57.1
60	50.2-69.8	53.1-66.9
70	60.8-79.2	63.6-76.5
80	72.0-88.0	74.3-85.7
90	84.0-96.0	85.8-94.2

For percentages of 5 or less the limits were derived assuming a Poisson rather than a binomial distribution.

From Cartwright,<sup>11</sup> courtesy of the author and Grune & Stratton

(100 $\times$ ) and this area is then examined in detail under oil-immersion magnification (approximately 1000 $\times$ ). The numbers of neutrophils, eosinophils, basophils, lymphocytes, monocytes, and other leukocytes, if present, are recorded and the proportion of each is calculated. The error in such estimates of cell percentage is considerable because only a very small sample (100 or 200 cells) of a large population (more than 5000) is examined.

Distributional errors are reduced as more cells are enumerated. Confidence tables or curves from which one may estimate the probable error of a differential count when various numbers of cells are counted are available.<sup>150,153</sup> Table 6-3 shows 95% confidence limits. It is evident that as more cells of a given type are counted and as the total number of cells enumerated increases, the accuracy of the differential count is greater. Thus, if 200 cells are counted and a frequency of 70% is found for a given cell type, the true value can be expected to lie between 63.5 and 76.5% for 95% of such counts. If a subsequent 200-cell differential count gave

a figure of 80% for that cell type, this would indicate that the difference is probably real, while if only 100 cells had been counted the difference would probably not be significant. Even so, if one is dealing with cells present only in small numbers (such as eosinophils or basophils in the usual smear) the values obtained from the differential count provide only a gross estimate of cell frequency. For more accurate enumeration of these cell types, absolute counting methods have been developed<sup>663,674,720,731</sup> (see pages 263, 266).

From the total leukocyte count (Chapter 1) and the differential count the absolute concentration of each leukocyte type can be calculated. The accuracy of the result depends on the validity of the total leukocyte count and the differential count. With present-day, automatic cell counters (see Chapter 1) the major component of error now lies in the differential count.

Normal values for absolute leukocyte concentrations are shown in Table 6-4. The absolute leukocyte concentration provides a more accurate picture than the differential count because, in essence, each leukocyte type is a separate cell system with its own functions, control mechanisms, and responses to disease processes; eg, a patient with chronic lymphocytic leukemia whose total leukocyte count is  $100 \times 10^9$  cells/l, 7% of which are neutrophils and the remainder lymphocytes, does not have granulocytopenia. His blood neutrophil concentration is  $7.0 \times 10^9$  cells/l, his problem is marked lymphocytosis.

Various "systems" for differential counting were employed at one time<sup>151</sup> (Fig. 6-7). Arnett,<sup>9</sup> for example, painstakingly recorded, and tabulated from left to right, the number of neutrophilic leukocytes with 1, 2, 3, etc lobes and made other subdivisions. The term "*shift to the left*" is derived from this practice and indicates an increase in the proportion of cells with only one or very few lobes, whereas "*shift to the right*" represents an increase in the proportion of multisegmented forms. Schilling used the term "*regenerative shift*" to refer to the increased proportion of juveniles and myelocytes that appear in the blood in response to an acute process, and "*degenerative shift to the left*" to indicate a

failure to mature as a result of depressed marrow function. He pointed out that when the "*shift*" is of the latter type an increased number of immature forms is found in the blood, but the nuclei of these cells are narrow, T-, V-, or U-shaped, deeply stained, and show little structural detail ("*Stabkernige*" or "*staff*" cells).<sup>152</sup>

From a clinical viewpoint it is now appreciated that it is useful to determine whether or not young forms of neutrophils (band forms and younger) are increased and whether there is an increased proportion of multinucleated forms. An increase of younger forms (band cells, metamyelocytes, and myelocytes) ("*shift to the left*") suggests increased release of young neutrophils from the bone marrow; this is seen in association with acute infections<sup>50</sup> and inflammation (see Chapter 41). If there appears to be a "*shift to the right*" it may be useful to make a *neutrophil lobe count*. This involves counting the total number of nuclear lobes in 100 or 200 neutrophils, calculating the average lobe number per neutrophil, and comparing the results with normal values. The chief difficulty here is clear definition of what constitutes a separate lobe (see page 231). If complete separation of nuclear lobes with or without a connecting filament is the definition used, the normal mean neutrophil lobe count is 2.04, with 95% of normal values falling between 1.66 and 2.42.<sup>53</sup> An increase in mean neutrophil lobe count suggests vitamin B<sub>12</sub>

**Table 6-4. Absolute Blood Leukocyte Concentrations in 291 Normal Adults\***

Cell Type	Median	95% Limits
Total leukocytes	7.0	4.3-10.0
Band neutrophils	0.52	0.1-2.1
Segmented neutrophils	3.0	1.1-6.05
Total neutrophils	3.65	1.83-7.25
Lymphocytes	2.5	1.5-4.0
Monocytes	0.43	0.2-0.95
Eosinophils	0.15	0-0.7
Basophils	0.03	0-0.15

\*Values expressed in cells  $\times 10^9$ /l. Leukocyte counts performed with an electronic counter (Coulter model A or F). At least 200 cells were enumerated for each differential count.

From Orfanakis et al,<sup>53</sup> courtesy of the authors and The American Journal of Clinical Pathology

Fig. 6-7. Diagram illustrating several classifications of the neutrophils. Note that all the classifications agree on a common dividing line between mature and immature cells. The Schilling classification further subdivides only the immature cells. The Cooke and Ponder and the Arneith classifications further subdivide only the more mature cells. (From Haden<sup>151</sup>)

or folic acid deficiency, congenital hypersegmentation of neutrophils, or renal disease.<sup>33</sup> A ratio of five-lobed to four-lobed polymorphonuclear cells that is greater than 0.17 was said to be more regularly associated with  $B_{12}$  deficiency than is an increase in mean nuclear lobe count.<sup>28</sup>

Alterations in the total number of leukocytes and in their relative proportions are of considerable significance as measures of the reactions of the body to noxious agents. Thus, in addition to noting the presence of young or multilobed neutrophils, the presence of increased numbers of promonocytes<sup>111</sup> or "stimulated" lymphocytes in the blood smear is indicative of certain disease processes. The reactions of leukocytes in disease will be discussed in Chapters 41 and 42 as will the presence of abnormal inclusions such as "toxic" granulation, Döhle bodies, and various inherited abnormalities in leukocyte morphology.

An additional special type of differential cell count which is in common use is the histochemical, semiquantitative estimate of the leukocyte alkaline phosphatase content of neutrophils.<sup>38</sup> In this procedure a fresh blood

smear is overlaid with an incubation mixture containing a substrate such as naphthol AS-BI phosphate, which is hydrolyzed by the alkaline phosphatase present in the normal "specific" neutrophil granules (see Chapter 1, page 28). The hydrolyzed product is coupled to a salt to form an insoluble red dye (Plate XV) and the intensity of the staining is graded 0 to 4+. After grading 100 neutrophils and recording the numbers of cells graded 0, 1+, 2+, etc, the product of the number of cells in each category and the category number (eg,  $2+ \times 20$  cells) is obtained, and the sum of these products is totaled. A maximum score is 400 and the usual normal score is about 25 to 140.<sup>18</sup>

### Leukocyte Kinetics (Dynamics of Production, Circulation, and Turnover) and Cell Function

Although the role of leukocytes in the defense of the organism has been known since the studies of Metchnikoff in 1892, and it is evident that each of the several leukocyte cell

lines has special properties and a unique role in body defense, the details and mechanisms by which the functions of leukocytes are accomplished still are incompletely understood. Basic to the accomplishment of the roles are cell multiplication, maturation and storage, and delivery via the blood to the tissues and sites of infection or cell damage. These processes are referred to as *leukocyte kinetics* and are different for each leukocyte type. It will simplify the discussion to consider each type of leukocyte as a separate system, but it must be realized that the several systems constantly interact and complement one another in the defense of the body.

### Neutrophil Series—Kinetics, Properties, and Functions

In Chapter 2 the process of mitotic cell division, the cell generation cycle, and the origin of neutrophils and other cell types from a multipotential colony-forming unit (CFU) cell were discussed. The CFU cell is thought to produce a "committed" stem cell (CSC) from which in turn the myeloblast is formed and from this the neutrophilic series is derived. The production, kinetics, and

life span of the neutrophil have been the subject of a number of reviews.<sup>176,181,186,189,190,191,213,252,258,279,260,263,282,284</sup> A model describing these processes is shown in Figure 6-8.

### The Mitotic and Maturation Compartments—Kinetics of Production and Turnover

Neutrophil production in normal adult man appears to take place only in the bone marrow. The life cycle of the neutrophil can be divided conveniently into bone marrow, blood and tissue phases. It is assumed that cells move through the system in a more or less orderly manner as if in a pipeline; this view is supported by the progressive movement of isotopic tracers<sup>70,195,247,259</sup> and azurophilic granules<sup>10,13,73</sup> through the system.

The myeloblast, promyelocyte, and myelocyte are capable of cell division, as judged by direct observation in cultures<sup>14</sup> and by their ability to incorporate tritiated thymidine into their nuclear DNA.<sup>182</sup> These forms therefore constitute the *mitotic compartment* (Fig. 6-8). They simultaneously undergo differentiation, as evidenced by the appear-

Fig. 6-8 Model of the production and kinetics of neutrophils in man. The marrow<sup>203</sup> and blood<sup>184</sup> compartments have been drawn to show their relative sizes. The compartment transit times as derived from DF<sup>33</sup>P studies<sup>184,282</sup> are shown on the next to the last line. Values derived from tritiated thymidine studies are shown on the last line.<sup>191</sup>

ance of azurophilic and specific granules in their cytoplasm. The more mature forms of the neutrophil series (metamyelocyte, band, and polymorphonuclear neutrophil) are usually considered to be incapable of cell division (except perhaps in unusual circumstances<sup>245</sup>) and do not incorporate tritiated thymidine into their nuclei, but they do exhibit continuing maturational changes and thus constitute the *maturation compartment*. From the maturation compartment, cells flow into the blood where they are distributed in two sites: (1) the circulating blood granulocyte pool (CGP), or (2) the marginal granulocyte pool (MGP), where they adhere to the walls of postcapillary venules. Cells in these two sites are in continual equilibrium. Eventually the cells move through vessel walls to enter the tissues.

In such a scheme, cell production can be estimated either by assessing the production ("birth") rate in the mitotic compartment or by measuring cell flow through subsequent stages such as the blood. These measurements are facilitated if the system is studied in the steady state when compartment sizes are constant and cell flow reflects net production and destruction.<sup>243</sup>

It is apparent that if one assumes a steady state in a scheme such as that shown in Figure 6-8, the flow of cells out of any pool ( $K_{out}$ ) is equal to the flow of cells into that pool ( $K_{in}$ ) plus any cells produced ("born") in the pool ( $K_b$ ); thus

$$K_{out} = K_{in} + K_b$$

Obviously, in pools other than those in the mitotic compartment,  $K_b$  is zero, and measurements of cell flow ( $K_{in}$  or  $K_{out}$ ) will equal effective cell production provided no cell death occurs within the pool.

### Production in the Mitotic Compartment

Since myeloblasts, promyelocytes, and myelocytes comprise about 0.9%, 3.3%, and 12.7% of the marrow cells, respectively (Table 2-1, page 62), it has been assumed that there are four or five divisions in the system.<sup>232</sup> From blood neutrophil radioac-

tivity curves obtained after DF<sup>32</sup>P injection into man it was suggested that there must be at least three divisions at the myelocyte stage.<sup>232</sup> It was also suggested from marrow differential counts that only four or five divisions occur in the entire neutrophil proliferation scheme.<sup>232</sup> This is in agreement with experiments in dogs<sup>261</sup> and with data from model studies.<sup>238</sup> In contrast, studies of myeloid islands in the rat thymus provided evidence for seven divisions during granulocytogenesis: one in the myeloblast stage, two in the promyelocyte stage, three in the myelocyte stage, and a final one in the metamyelocyte stage.<sup>274,275</sup>

Calculations made from *mitotic index* data<sup>191,210,232,233,234,240</sup> provide estimates of cell generation time ( $t_g$ ) and pool turnover time. *Mitotic index*<sup>210,240,241</sup> is defined as:

$$MI = \frac{N_m}{N}$$

where MI is the mitotic index for any morphologic cell pool,  $N_m$  is the number of mitoses in that pool, and  $N$  is the total number of cells in the pool. MI can also be expressed as the ratio of the time spent in mitosis ( $t_m$ ) to the cell generation time ( $t_g$ ):

$$MI = \frac{t_m}{t_g}$$

Combining both definitions:

$$MI = \frac{N_m}{N} = \frac{t_m}{t_g}$$

It is apparent that, by providing determined values for mitotic index and mitotic time in the last equation, the generation time ( $t_g$ ) for a particular cell pool can be approximated. From  $t_g$  and the pool size ( $N$ ) the birth rate,  $K_b$ , can be obtained if all cells in the pool are in cycle, since each mitosis gives rise to one new cell:

$$K_b = \frac{N}{t_g}$$

In effect the cell birth rate is equal to the number of mitoses occurring per unit time, or

$$K_b = \frac{N_m}{t}$$

Although the concept is simple, several problems arise.<sup>232,233</sup> A major one is that the morphologic boundaries of most cell pools are not clearly delineated in terms of the cell cycle.<sup>233</sup> For example, to calculate cell production in the myelocyte pool it must be assumed that all myelocytes are destined to divide; that is, that there are no cells recognized as myelocytes that are not going to divide again. Since the daughter cells of the last myelocyte mitosis almost certainly do not suddenly become metamyelocytes on completion of division,  $N_m$  in the above equation will be erroneously large and estimates of  $t_c$  will be erroneously long.

If the fraction of nonmitotic cells in the myelocyte population were known, the calculations could be corrected for this error, and this has been attempted.<sup>186</sup> A second major problem is the fact that values for the mitotic index have varied from 6.93 to 43 per 1000 nucleated cells in man,<sup>193,200,210,225,232,240</sup> 28% to 48%<sup>210,228,232,250</sup> of these being in the leukocytic system. In addition, there appears to be considerable diurnal variation in the mitotic index in man<sup>232,250</sup> as well as in animals.<sup>219</sup> Finally, in order to calculate the absolute neutrophil production rate (in cells per unit of time) the size of the marrow cell pool under consideration must be known. Methods for measuring the sizes of marrow myeloid pools have been developed<sup>203,204</sup> (see page 248), but to date no one has measured these sizes and mitotic index in the same animal at the same time and then calculated neutrophil production rate. Nevertheless, values for the mitotic index for each of the mitotable neutrophil precursors have been determined,<sup>232,240</sup> and within the assumptions inherent in such calculations<sup>233</sup> neutrophil production has been estimated.<sup>234,258</sup>

Similar calculations of neutrophil production can be made from *tritiated-thymidine-labeling index* data. After flash labeling with <sup>3</sup>HTdR, autoradiographs of the bone marrow have been made and the proportion of nucleated cells that have incorporated the label into their nuclei has been determined.<sup>189,260</sup> This "labeling index" (LI) represents the ratio of labeled cells,  $*N$ , or cells in DNA

synthesis ( $N_s$ ) to total cells ( $N$ ) of a defined morphologic type:

$$LI = \frac{*N}{N} = \frac{N_s}{N}$$

The labeling index can also be defined in terms of DNA synthesis time ( $t_s$ ) and the cell generation time ( $t_c$ ) since <sup>3</sup>HTdR is taken into the cell only during the period of DNA synthesis; thus:

$$LI = \frac{t_s}{t_c}$$

By combining both definitions we have:

$$LI = \frac{N_s}{N} = \frac{t_s}{t_c}$$

and from determined values for LI and  $t_s$ , the generation time and turnover of a given cell population can be estimated. As with mitotic index data, birth rate is a function of the population turnover time which can be approximated from the generation time or time spent in various phases of the cell cycle:

$$K_b = \frac{N}{t_c} = \frac{N_s}{t_s}$$

Some of the same problems arise with the tritiated-thymidine-labeling index that are encountered in the use of the mitotic index.<sup>194,233</sup> In addition, the use of labeled compounds raises questions of label reutilization<sup>207,208</sup> or elution<sup>194</sup> and perturbation of the cell population by the compound<sup>170,216,220,222,261</sup> or by its radioactivity,<sup>225,272</sup> to cite just a few.<sup>194</sup>

The labeling indices reported for man are: myeloblast—0.85; promyelocyte—0.65, and myelocyte—0.33.<sup>189</sup> Somewhat different values have been reported in dogs<sup>260</sup> and rats.<sup>240</sup> By using the labeling indices for man and a value for  $t_s$  of five hours (based on studies in dogs) and by determining relative compartment sizes for each cell type from the bone marrow differential count, the relative birth rates ( $K_b$ ) of cells have been calculated.<sup>189,240</sup>

While some have found good agreement between neutrophil production as calculated from mitotic index and from labeling in-

dex,<sup>240</sup> considerable discrepancy has been reported by others.<sup>186</sup> This may be because: (1) the mitotic index values obtained were low, (2) the studies were done in different subjects at different times, and/or (3) too small a value for  $t_s$  was used in the calculations.

The turnover time of a labeled compartment and neutrophil production rate also may be estimated by measuring the *grain count halving time*.<sup>195</sup> This method will give the generation time only if each cell in a given class divides and if there is no label feeding into the compartment from a labeled precursor class or as a result of label reutilization.<sup>187</sup> If any of these criteria are not met the half-time for grain count decrease will be longer than the true value and the estimate of generation time is then only a maximal value. Additional disadvantages of this method are that at least several bone marrow samples distributed throughout several half-times are needed, and grain counting is extraordinarily tedious and subject to considerable error. Nevertheless, estimates of compartment

turnover time have been made with this method using  $^3\text{HTdR}$ <sup>195</sup> and radiolabeled sulfate.<sup>70</sup>

After flash labeling with  $^3\text{HTdR}$  the cohort of cells labeled during DNA synthesis may be followed as it subsequently enters mitosis and the time course of labeled mitoses can be recorded.<sup>187,279</sup> Theoretically such curves should permit measurement of the post DNA synthesis gap ( $G_2$ ), mitotic time ( $t_m$ ), DNA synthesis time ( $t_s$ ), cell generation time ( $t_c$ ), and pre DNA synthesis gap ( $G_1$ ) (see page 42, [Fig. 2-1] and Fig. 6-9). In actual practice, biologic variation rounds off the *percent labeled mitosis curves*, and rapid damping of the waves of cells passing through mitosis (Fig. 6-9) renders such measurements less precise than would be ideal. However, estimates of myeloid DNA synthesis time obtained with this method are about 11 to 13 hours in man<sup>187,279</sup> and are in good agreement with estimates made in gastrointestinal mucosal cells. From the level of the damped plateau reached after a few hours, the ratio  $t_s/t_c$  can be obtained (Fig. 6-9) and from this the generation time can be calculated. If one

Fig 6-9. Schematic diagram of the percentage of labeled mitoses in the course of cell generation. The top portion of the diagram shows the theoretical configuration that would be seen if cells flowed through the proliferation cycle with no variation. The effects of moderate variation in time spent in the several cycle phases on the percent labeled mitosis curve are shown in the bottom portion.  $G_1$  is pre-DNA synthesis resting phase (gap),  $S$  is the DNA synthetic period,  $G_2$  is the post DNA synthesis gap and  $M$  is mitosis.  $t_s$  is the time spent in  $S$ , and  $t_c$  is the duration of the entire generative cycle. (From Cronkite,<sup>187</sup> courtesy of the author, the Brookhaven National Laboratory and the National Cancer Institute.)

assumes that the generation time and compartment transit time are the same or if one knows the proportion of cells in a compartment that is actively proliferating, the neutrophil production rate can be calculated.

#### Neutrophil Production as Measured by Cell Flow in Other Compartments

Still another method for approximating neutrophil production is to follow the *appearance of  $^3\text{HTdR}$ -labeled cells in the metamyelocyte compartment*. Since metamyelocytes do not divide or take up  $^3\text{HTdR}$ , the appearance of labeled cells in this compartment should reflect the flow of cells into it from the myelocyte compartment; in the steady state this should also reflect the turnover of the metamyelocyte compartment and thus cell production. There is about a three-hour lag after the injection of  $^3\text{HTdR}$  before label appears in metamyelocytes both in dogs<sup>260</sup> and in man<sup>137</sup>; this time interval represents the minimum time for myelocytes taking up the label to pass through  $G_2$  and mitosis and to become metamyelocytes (see Chapter 2, page 42). After this lag, the rate of labeled cell inflow into the metamyelocyte compartment is about 3 to 5% per hour in both species.

In the dog, cell inflow into the metamyelocyte compartment measured in this fashion was less than 50% of that calculated from labeling index data.<sup>260</sup> This led Patt to suggest that there is a major component of ineffective granulocytopoiesis, a "*myelocyte sink*," in the normal animal. However, similar calculations in man have not confirmed the studies in dogs.<sup>186</sup> The resolution of this enigma will require the simultaneous measurement of cell production using several methods in the same animal at the same time.

Neutrophil production also can be approximated by measuring the flow of cells through the blood, the *blood granulocyte turnover rate* (GTR). Diisopropylfluorophosphate ( $\text{DF}^{32}\text{P}$ ) binds irreversibly with a number of esterase enzymes and has been shown to label neutrophils primarily.<sup>183,231</sup> By means of this label the total blood granulocyte pool (TBGP) can be measured (see below) and the rate of dis-

appearance of labeled neutrophils from the blood can be determined.<sup>232</sup> Since neutrophils leave the blood in a random manner (exponential disappearance curve) the GTR is calculated as follows from the total blood granulocyte pool (TBGP) and the  $t_{1/2}$ :

$$\text{GTR} = \frac{.693}{t_{1/2}} \times \text{TBGP}$$

where .693 is the natural logarithm of 2, and  $t_{1/2}$  is the blood neutrophil half-disappearance time. If there is no significant component of neutrophil death in the marrow, the blood GTR will equal total neutrophil production. If there is significant neutrophil death in the bone marrow, the blood GTR measures *effective neutrophil production* and the difference between this and total neutrophil production is *ineffective granulocytopoiesis*. Measurements of neutrophil production by this method gave values ranging from 62 to  $400 \times 10^7$  neutrophils/kg/day in man<sup>174</sup> (Table 6-5) and 150 to  $560 \times 10^7$  neutrophils/kg/day in dogs.<sup>260</sup>

Of the above methods for assessing neutrophil production only the measurement of blood neutrophil turnover rate with  $\text{DF}^{32}\text{P}$  can be carried out with sufficient facility to be of use in studying groups of patients in a clinical setting, and even this is possible in only a few research centers.

#### Size of the Marrow Compartments and Their Morphologic Subdivisions

In all of the above procedures except the  $\text{DF}^{32}\text{P}$  measurements it is necessary to know the number of marrow myeloid cells under study in order to calculate neutrophil production. In the absence of such data only calculations of relative cell production are possible.<sup>186</sup> Direct measurements of the volume and cellularity of the marrow have been made in rats,<sup>230</sup> mice,<sup>257</sup> and guinea pigs,<sup>223,224</sup> but such studies are not possible in man. The  $^{59}\text{Fe}$  dilution technique for measuring the marrow nucleated red cell mass, from which myeloid mass can be calculated by using the myeloid:erythroid ratio, provides the best estimates of marrow cellularity for man and several other spe-

cies.<sup>203,204,257,280</sup> The mean values obtained in nine male patients undergoing thoracotomy for tuberculosis are presented in Figure 6-8. Values determined in rats, rabbits, and monkeys also have been reported.<sup>201</sup>

### Transit Time through the Nondividing Maturation Pool

Following a pulse label of tritiated thymidine or radiophosphate there is a delay of several days before labeled segmented neutrophils appear in the blood. This represents the minimum time from DNA synthesis in the last myelocyte generative cycle until the cell has matured into a segmented neutrophil (or band form) and is released into the blood. In patients in a "normal" steady state this minimum transit time or *emergence* time was between 96 and 144 hours<sup>213,264</sup>; in patients with infection it was as short as 48 hours. Emergence time in dogs is 2 to 3 days<sup>215</sup> and in the rat 36 to 42 hours.<sup>211</sup>

The mean value for *myelocyte-to-blood transit time* after DNA labeling (the time from <sup>3</sup>HTdR or radiophosphate injection to the peak of the blood granulocyte radioactivity curve) is 6 to 9 days in hematologically "normal" convalescent patients. In contrast, studies in which DF<sup>32</sup>P was injected intravenously into normal volunteers (prisoners) led to the conclusion that the mean myelocyte-to-blood transit time was 11 days with a range of 8 to 14 days.<sup>184,282</sup> Studies using <sup>3</sup>HTdR and DF<sup>32</sup>P simultaneously in the same subjects demonstrated that these discrepancies reflected differences between normal, ambulatory subjects and hematologically "normal," convalescent patients.<sup>172</sup> In dogs the average myelocyte-to-blood transit time was 5 days as measured with both <sup>3</sup>HTdR and DF<sup>32</sup>P.<sup>172</sup>

### Manner of Segmented Neutrophil Release from the Marrow into the Blood<sup>277</sup>

After <sup>3</sup>HTdR injection and at the time when label was first seen in band and segmented neutrophils in the bone marrow, some labeled cells were also seen in the

blood.<sup>189</sup> From this it was suggested that the release of band or segmented neutrophils from the marrow does not follow a strict pipeline or first-in-first-out sequence.<sup>189,213</sup> However, it is not clear whether these observations reflected variance around a mean transit time,<sup>178,248,282</sup> or random release of mature neutrophils from the marrow.<sup>213</sup> Studies in dogs strongly favor the mean transit time concept rather than random release.<sup>218</sup>

### Neutrophil Kinetics in the Blood

For a long time it has been accepted that neutrophils emigrate from the blood and are continuously replaced,<sup>271</sup> but it has not usually been appreciated that a large proportion of granulocytes in the blood are not in the main stream of the circulation. It is well known that various physiologic influences such as exercise, excitement, and other factors may be associated with a substantial increase in the leukocyte count,<sup>309</sup> and this was long attributed to release of leukocytes sequestered in the spleen. However, various observers have recorded the fact that such changes also occur in splenectomized persons.

### DF<sup>32</sup>P Studies

With the development of the DF<sup>32</sup>P-labeling technique, in which neutrophils are labeled *in vitro* with DF<sup>32</sup>P and the undamaged cells are returned to their donor, it was demonstrated that there are two "pools" of neutrophils in the blood, a circulating granulocyte pool (CGP) and a marginated granulocyte pool (MGP).<sup>165,168,252</sup> In normal man, neutrophils in these two sites are in constant equilibrium and the pools are of about equal size (Table 6-5). The CGP is calculated from the blood leukocyte count and the blood volume. TBGP is measured by the dilution of DF<sup>32</sup>P-labeled neutrophils after their re-injection.<sup>165</sup> MGP is the difference between TBGP and CGP.

Brief exercise or epinephrine injection increases the size of the circulating granulocyte pool by about 50%, but the TBGP is unchanged; the neutrophilia so produced reflects

Table 6-5. Blood Neutrophil Kinetic Parameters in 71 Normal Subjects

	Mean	95% Limits
TBGP (cells $\times 10^7$ /kg)	61	27-128
CGP (cells $\times 10^7$ /kg)	31	13-49
MGP (cells $\times 10^7$ /kg)	29	8-115
$T_{1/2}$ (hours)	6.3	4-10
GTR (cells $\times 10^7$ /kg/day)	160	62-400

Based on data from Bishop et al.<sup>174</sup>

a demargination of cells which lasts only a few minutes.<sup>165</sup> The location of the margined cells is thought to be along the walls of small blood vessels, primarily postcapillary venules, in many body tissues.<sup>281</sup> The distribution of cells in the CGP and MGP can be altered by other means. For example, after endotoxin injection a transient neutropenia was noted at 90 minutes but the TBGP was not significantly changed; thus there was mainly a shift from CGP to MGP. At the end of five hours, there was a marked increase in the TBGP as a result of an outpouring of cells from the bone marrow, and the CGP and MGP were of about equal size.<sup>166</sup> The administration of steroids also produced an increase in the size of the TBGP, in part for the same reason but also because of decreased outflow into the tissues.<sup>173</sup>

After the return of DF<sup>32</sup>P-labeled neutrophils to their donor the disappearance of labeled cells from the blood follows a single exponential curve with a *half-disappearance time* ( $t_{1/2}$ ) of about seven hours in most normal subjects.<sup>161,167,168,184,217,252</sup> This implies that neutrophils are destroyed or leave the blood randomly rather than according to their age (senescence), as is the case for erythrocytes and platelets.<sup>252</sup> Confirmation of this is found in the fact that <sup>3</sup>HtDR-labeled neutrophils appear in the blood and in saliva almost simultaneously.<sup>212</sup>

From leukopheresis<sup>295</sup> and other experiments<sup>251</sup> it is probable that neutrophils that have crossed the endothelial barrier between blood and tissues do not reenter the circulation, at least in significant numbers. The number of neutrophils that pass through the blood each day has been found to be

$160 \times 10^7$  cells/kg/day (Table 6-5); this is the granulocyte turnover rate (GTR). It has been proposed that neutrophils become senescent and develop pyknotic nuclear lobes as time elapses, this process truncating the exponential curve of disappearance of DF<sup>32</sup>P-labeled neutrophils.<sup>212</sup> Although this seems plausible, no truncation of DF<sup>32</sup>P curves has been noted. Perhaps this is because pyknotic, senescent cells constitute only 0.5% of neutrophils and detection of their early removal could be easily missed.

### <sup>51</sup>Cr Studies

Leukocytes can also be labeled in vitro with radiochromate (<sup>51</sup>CrO<sub>4</sub>) and then returned to the body.<sup>205,254,255</sup> Unlike DF<sup>32</sup>P, which labels mainly granulocytes, leukocyte types other than neutrophils are labeled by this technique.<sup>201,205,206,255,256,264</sup> Under some circumstances (eg, in chronic lymphocytic or chronic myelocytic leukemia) this is advantageous since leukocytes other than neutrophils can be labeled and their distribution and turnover followed.<sup>201,205,256</sup> In addition, <sup>51</sup>Cr is a gamma-emitting isotope and thus external counting techniques should be helpful in locating sites of sequestration or destruction. After the infusion of autologous, radiochromate-labeled leukocytes into hematologically normal subjects the proportion of cells recovered in the blood is considerably less than that of DF<sup>32</sup>P-labeled neutrophils.<sup>255</sup> This may reflect early elution of part of the label,<sup>270</sup> or perhaps the rapid disappearance of <sup>51</sup>Cr-labeled mononuclear cells. However, after an initial rapid decrease, curves of <sup>51</sup>Cr-labeled leukocyte radioactivity in the blood have given  $t_{1/2}$  values quite comparable to those obtained with DF<sup>32</sup>P. No significant organ sequestration of labeled leukocytes has been detected in normal subjects.<sup>255</sup>

### Neutrophil Migration into Tissues and Sites of Destruction

The sites into which neutrophils normally disappear are poorly understood. Labeled blood neutrophils are found in oral saliva,<sup>211</sup>

but loss into saliva may reflect subclinical infection since few if any cells are found in the salivary ducts<sup>227</sup>; the rate at which granulocytes enter the oral cavity has been correlated with the degree of gingivitis.<sup>236</sup> Nevertheless, some cells do penetrate the oral mucosa in healthy persons, presumably as a result of diapedesis.<sup>227</sup> Loss of leukocytes in the urine also has been demonstrated in normal subjects<sup>160</sup>; this increases markedly in pyelonephritis.<sup>218</sup> In addition, arteriovenous catheterization studies in dogs<sup>162</sup> and man<sup>171</sup> have provided evidence that suggests that leukocytes also are removed through the lungs, in the liver and spleen. Significant numbers may be lost into the gastrointestinal tract. No quantitative data concerning the rate of loss through these various organs are available. That loss via subclinical infections at the various body surfaces is not a major factor in neutrophil turnover is suggested by the observation that bone marrow and blood leukocyte counts were essentially the same in germ-free and in normal mice.<sup>179,214</sup>

At a local site of tissue damage or infection, adherence of neutrophils to the endothelial cells of the vessel wall and their subsequent emigration into the tissues can be seen within minutes. Although it has been suggested that chemotaxis offers the best explanation for the *adherence and emigration*, there is no proof that this is the case.<sup>458</sup> After the initial sticking the neutrophils can be seen to project pseudopods between the endothelial cells and to force a passage between them.<sup>434,446</sup> Further migration is then delayed by the basement membrane and periendothelial cells, and the neutrophils may move parallel to but beneath the endothelium until a passage into the surrounding connective tissue is found. There is no evidence of neutrophil granule lysis to suggest that a passage is made by dissolving interendothelial cell cement substance or collagen fibrils and there is no consistent morphologic evidence of change in the endothelial cells.<sup>434</sup> Whether similar mechanisms operate under normal conditions is not known. Once neutrophils leave the blood they do not return in significant numbers.<sup>177,231</sup>

### Normal Values and Physiologic Variations

The changes in blood leukocyte concentration that occur with growth and development were described in Chapter 2 and shown in Figure 2-11. By the age of four to eight years the blood differential cell count approaches that seen in the adult. Normal values for adults are presented on page 242. These values were determined by using anticoagulated blood and electronic counters, but the results are essentially identical to those obtained by hemocytometer methods over 30 years ago.<sup>321</sup> Metamyelocytes or myelocytes are not often seen on routine examination of the blood smear, but a few such cells can be found in normal blood by careful search or, more readily, by examination of buffy coat smears (3.6/3000 granulocytes)<sup>299</sup>; atypical mononuclear forms and megakaryocyte fragments containing nuclei are seen in such smears also. Whether there is a significant difference in leukocyte concentration between the sexes or with *advancing years* is not clear since reports are conflicting.<sup>290,303,319,329</sup> There probably is no difference between *races*<sup>55</sup> but this topic has not been studied extensively.

Although leukocyte concentration is maintained within definite limits in normal man, fluctuations occur during a single day as well as from day to day and periodic cycling at longer intervals has been reported<sup>315</sup> (see below). The suggestion that there is a characteristic hourly rhythm has not been confirmed<sup>294,310</sup> nor has the occurrence of a "digestive" leukocytosis been established.<sup>333</sup> Light influences the diurnal variation.<sup>327</sup> Under conditions of complete *physical and mental relaxation* a basal level of 5.0 to  $7.0 \times 10^9$  cells/l is usual.<sup>306</sup> Ordinary *activity* may be associated with a moderate increase and a somewhat higher level is common in the afternoon. Under all these conditions, however, the leukocyte count tends to remain within the range of "normal" (Table 6-4).

Conclusive demonstration of the effects of *climate or season* on the leukocyte count is lacking. It was claimed that meteorologically

conditioned fluctuations occur.<sup>324</sup> Heat and intense solar radiation are said to cause leukocytosis.<sup>309</sup> Artificially induced heat causes lymphocytosis.<sup>302</sup> Sunlight and ultraviolet radiation are reported to cause lymphocytosis. Acute *anoxia*, both anoxic and anemic, causes leukocytosis.<sup>297</sup> This is neutrophilic in type and does not develop in adrenalectomized rats. In the first few days after an individual has arrived at a high altitude, some leukocytosis, accompanied by lymphopenia and eosinopenia, has been observed. Slight lymphocytosis and eosinophilia soon develop, however.<sup>332</sup>

Marked leukocytosis regularly occurs with *strenuous exercise*. Counts as high as  $22.0 \times 10^9/l$  have been recorded for a runner after making a 100-yard dash in 11 seconds, and  $35.0 \times 10^9/l$  on completing a quarter-mile run in less than a minute.<sup>306</sup> The increment of cells usually is made up mainly of segmented neutrophils, but lymphocytosis may be prominent as well. Such leukocytosis recedes to normal in less than an hour and in the case of the neutrophils is due to a shift of cells from marginal sites (MGP) to the circulation (CGP) ("*shift*" leukocytosis).<sup>165,166</sup> This leukocytosis occurs in the absence of the spleen and thus the spleen is not a major site of cell margination. Leukocyte counts above  $20.0 \times 10^9/l$ , mainly neutrophils, are regularly recorded for runners completing a marathon of 26 miles in two and one-half to three hours; there is disagreement as to whether a shift to the left, suggesting mobilization of marrow neutrophils, occurs in this circumstance.<sup>306</sup> Postmarathon run leukocytosis subsides slowly over a number of hours and probably reflects a redistribution of granulocytes in the blood, as mentioned above, combined with mobilization of cells from the marrow with an increase in TBGP size. The magnitude of the leukocytosis associated with exercise appears to depend primarily on the intensity of the activity rather than upon its duration.<sup>300</sup>

*Convulsive seizures*, from whatever cause, are associated with increases in leukocyte count similar to those following violent exercise. Electrically induced convulsions are fol-

lowed by a reduction in eosinophils and lymphocytes and a rise in neutrophils, findings interpreted as consistent with the effects of adrenal hormone secretion.<sup>291</sup> *Epinephrine* injection produces a leukocytosis the nature and duration of which appear to vary with the mode of administration. Intramuscular injection causes leukocytosis in two phases<sup>304,326</sup>; in the first, which is maximal at 17 minutes, the number of neutrophils, lymphocytes, and eosinophils increases and subsequently returns toward normal over several hours. This almost certainly represents a shift leukocytosis. In the second phase the number of neutrophils rises again at about four hours, while the number of lymphocytes and eosinophils remains at or below pre-injection levels<sup>326</sup>; this phase may reflect an adrenal steroid effect and consists of an absolute neutrophilia. After intravenous injection a brief leukocytosis peaking at 5 to 10 minutes and of total duration of less than 20 minutes occurs and has been shown to be purely a shift neutrophilia.<sup>165,166</sup> The leukocytosis which follows subcutaneous injection is more variable.

During attacks of *paroxysmal tachycardia*, leukocytosis with cell counts of  $13.0$  to  $22.0 \times 10^9$  cells/l has been reported.<sup>312</sup> *Pain*, *nausea* and *vomiting*, and *anxiety* may cause leukocytosis in the absence of infection.<sup>314</sup> The lack of an increase in the number of band forms and metamyelocytes indicates that the neutrophilia is due to the redistribution of the cells between the marginal and circulating pools.

Either *anesthesia* produces leukocytosis; emotional and reflex reactions and struggling during the stage of excitement probably are responsible. Narcosis with barbitol compounds usually reduces the leukocyte count.

During the ovulatory period, eosinopenia and a slight rise in the number of leukocytes as well as increased levels of 17-hydroxycorticosteroids have been reported.<sup>298,322</sup> Slight leukocytosis occurs during *pregnancy*, and neutrophilia increases as term approaches.<sup>295</sup> The onset of labor is accompanied by neutrophilic leukocytosis, which sometimes is very pronounced ( $34.0 \times$

$10^9/l$ ). This continues for a day after delivery, only receding to normal after four or five days. These changes are accompanied by a reduction in the number of circulating eosinophils.<sup>298</sup>

Many of the physiologic variations in leukocytes which have been described above can be explained as manifestations of stimulation of the adrenal cortex. The administration of cortisone or hydrocortisone results in increased blood levels of 17-hydroxycorticosteroids that attain their maximal increase in one hour<sup>318</sup> and are associated with neutrophilia.<sup>307</sup> This is succeeded by eosinopenia and lymphopenia that become maximal in four to eight hours and bear a close relation to the quantity of hormone administered. The neutrophilia was observed to be less constant than the changes in eosinophils and lymphocytes, and it was not well correlated in time or degree to the changes in these cells. These changes probably can be attributed to the decreased efflux of neutrophils from the blood and the increased cell release from the bone marrow,<sup>166,173</sup> mentioned above (page 250) which are associated with the administration of steroid hormones, as well as to their effects on eosinophils and lymphocytes, as described below.

In addition to the above-mentioned short-term changes in neutrophil concentration a long-term oscillation in granulocyte count with a cycle length of 14 to 23 days was reported in 7 out of 11 male subjects.<sup>315</sup> The oscillation amounted to  $\pm 0.50$  to  $0.75 \times 10^9$  cells/l around mean values of between  $2.0$  and  $4.0 \times 10^9$  neutrophils/l. These findings have not been confirmed in studies in our laboratory and elsewhere.<sup>297a,313</sup>

### Control Mechanisms Regulating Granulocytopoiesis

From the above considerations it is evident that a truly steady state exists only for brief periods of time. Shifts of cells between marginal and circulating sites may occur without changes in blood neutrophil turnover,<sup>166</sup> but any change in TBGP size must result from changes in cell inflow and/or egress. Studies

based on the technique of leukopheresis have shown that the normal animal replenishes the TBGP after its depletion by mobilizing cells from the marrow granulocyte reserves.<sup>295</sup> This increase in neutrophil concentration and TBGP size, as well as increases that develop with most bacterial infections or after endotoxin or steroid administration, must be triggered by some signal, and there must also be some means of stimulating cell production to replenish the depleted marrow reserves. Neural mechanisms controlling hematopoietic cell proliferation and release have been suggested<sup>215</sup> as well as neutrophil-regulating substances that may be humoral in nature.<sup>341,364,366</sup> A granulocytosis-promoting factor (GPF) was isolated from a mouse mammary tumor that produced a massive neutrophilia and extramedullary foci of myelopoiesis in the host, but this finding has not yet been confirmed.<sup>348</sup> Endotoxin effects were excluded by suitable controls, and similar activity was found in non-tumor tissue, especially kidney, of several species. It was postulated that GPF may be a naturally occurring granulocytopoietic substance.<sup>348</sup> Partial characterization revealed it to be a micro-molecule ( $<2,000$  mol. wt.) free of protein. It was not found to deplete marrow neutrophil stores and therefore would appear to be different from neutrophilia-inducing factor and leukocytosis-inducing factor mentioned below.

In studies of perfused rat hind limbs the release of neutrophils from the marrow into the blood<sup>353</sup> was increased by a high perfusion flow rate or when the leukocyte content of the perfusate was low.<sup>350</sup> Serum from rats made neutropenic by endotoxin injection was found to be more effective than normal serum in causing neutrophil release, and such a leukocytosis-inducing factor (LIF) was found in the plasma of rats three to four hours following typhoid vaccine administration<sup>351</sup> but not before three hours.

A similar and perhaps identical activity was found in the plasma of dogs recovering from vinblastine- or nitrogen mustard-induced neutropenia or after endotoxin administration in animals<sup>341,342</sup> and in man.<sup>180</sup> The activity

was present during the period of neutropenia and rising neutrophil concentration, but not before or after this period. The activity ("neutrophilia-inducing activity", NIA) was qualitatively dissimilar from that following endotoxin, epinephrine, or cortisone administration and acted by causing release of marrow cells. Dog NIA was found to produce neutrophilia in endotoxin-tolerant, recipient dogs. These studies suggest that there is an endogenously produced humoral factor (NIA or LIF) that causes neutrophil release from the marrow.<sup>342</sup> How this release may be effected is not understood.

Injection of endotoxin has been shown to produce neutrophilia, usually preceded by neutropenia,<sup>340</sup> as discussed earlier (page 250). Detailed studies of the bone marrow during endotoxin-stimulated neutrophil release demonstrated changes in the adventitial cells of the sinusoid wall and marrow interstitium, a decrease in basement membrane substance, and lysosomal disruption in endothelial cells with occasional cell lysis.<sup>369</sup> However, cause and effect could not be distinguished.

Differences in cell deformability that occur with increasing maturity cannot be excluded as influencing the marrow cell release.<sup>46,47,354</sup>

Other studies have demonstrated an inhibitor of marrow neutrophil proliferation (*granulocytic chalone*) in the mature neutrophils and serum of the rat. This could provide a means for negative feedback control of granulocyte proliferation in the mitotic compartment. This activity was found to be specific for the granulocyte system but not species specific. Although of small molecular weight (about 4000) this inhibitor did not act on thymidine metabolism<sup>366</sup> as did a previously reported inhibitor, thymidine phosphorylase.<sup>356</sup> Stimulating activity (antichalone) was also described (mol wt 30,000 to 35,000). In situations of increased demand for neutrophils, chalone in the serum was reduced while antichalone was increased. Both substances appeared to act in the G<sub>1</sub> phase by inhibiting (chalone) or stimulating (antichalone) the entry of neutrophil precursors into DNA synthesis, and both effects were transient and reversible.<sup>367</sup>

Stimulation of granulocyte colony formation in agar plate cultures has been studied extensively.<sup>345,357,360</sup> Such *colony-stimulating activity* (CSA) can be produced by kidney or embryo cell feeder layers, salivary gland, pregnant uterus, and a variety of other tissues such as spleen, liver, lung, brain, testis, and thymus.<sup>346</sup> CSA was present in higher concentration in leukemic AKR mice than in preleukemic mice of the same strain or in other non-leukemic mice.<sup>362</sup> It was present in the sera of mice infected with viruses as well. Germ-free mice had little CSA in their sera as compared to conventionally housed mice. Similar activity has been found in the serum and urine of patients with acute or chronic leukemia or infectious mononucleosis, and in low concentration in normal persons. Partial characterization of CSA from several sources (mouse serum, human urine, mouse embryo cells) revealed similar molecular weights (45 to 100,000<sup>345,368</sup>), resistance to heat at 60°C for 30 minutes, and no loss of activity on dialysis. In mouse embryo extracts an inhibitor could be removed by dialysis, thus increasing CSA activity. Mouse CSA has shown some specificity in that marrow, spleen, fetal liver, and blood cells were stimulated to produce granulocyte colonies, but other tissue cells were not, nor were rat marrow cells stimulated. The polymorphonuclear neutrophils of man appear to secrete CSA and provide a better stimulus for human marrow colony growth than does urinary CSA. Blood leukocytes from patients with acute myeloblastic leukemia had little CSA activity.<sup>360</sup> In other studies, macrophages or monocytes were shown to release CSA whereas neutrophils were inhibitory.<sup>346a,328</sup> CSA was thought to act on the committed stem cell rather than on the more primitive CFU cell or later forms<sup>357</sup> (Fig. 6-8). Fluctuations in CSA content in animal or human serum and urine suggest that CSA has physiologic importance,<sup>347,361</sup> but this has not been clearly established as yet since CSA studies have been conducted almost entirely with the *in vitro* assay.

Still another granulocytopoiesis-stimulating factor has been described. This factor is active *in vivo*, diffuses into millipore cham-

bers to stimulate myeloid proliferation of blasts and promyelocytes, and is present only during the neutropenic and recovery phase which follows x-irradiation or vinblastine injection.<sup>364</sup> Preliminary studies suggest that its activity is not the same as that of CSA.

It is not yet clear how many of the factors described above represent separate and distinct control mechanisms of neutrophil production and release and which of them may be the same or closely related substances studied and assayed under different conditions and in different species.

### *Phagocytosis and Particle Ingestion*

The major function of neutrophilic granulocytes is to prevent or retard the intrusion of infectious agents and other foreign material into the host environment. This is accomplished by phagocytosis and digestion of the material. Neutrophils also release various substances into their environment and thus may have a secretory function as well.

*Endocytosis* is the process by which material is taken into a cell enclosed within pieces of plasma membrane without the material at any time occurring free in the cytoplasm of the cell (Fig. 6-10A).<sup>423</sup> Endocytosis is further divided into *pinocytosis* (drinking by cells) and *phagocytosis* (eating by cells). Phagocytosis can usually be seen by light microscopy while pinocytosis cannot because it involves ingestion of very small particles, such as macromolecules. Both processes involve invagination of the cell membrane and the formation of vesicles or vacuoles (phagosomes). Most cells appear capable of pinocytosis, but phagocytosis is a prominent activity of neutrophils, monocytes, macrophages, and, to a lesser extent, eosinophils and basophils. Like macrophages (page 272), polymorphonuclear neutrophils ingest foreign material (bacteria and a variety of particles), but they rarely ingest autologous cells<sup>462</sup>; similar particle selectivity appears to occur *in vivo*.<sup>102</sup>

Neutrophils and macrophages are motile and thus are free to migrate into sites of inflammation, apparently in a purposeful manner. Once in the area of inflammation

they come in contact with the foreign material, engulf it, and subject it to the bactericidal and digestive enzymes that they contain. This was first appreciated by Metchnikoff in the 1880's<sup>448</sup> when he observed the migration of phagocytes into areas of tissue damage in sponges and lower animals. From later studies he concluded that all resistance to infection resulted from the activities of phagocytic cells. However, work begun at about the same time demonstrated antibacterial activity in serum,<sup>412</sup> and by the early 1900's the concept that opsonins in the serum coat bacteria and render them easily ingested by phagocytes<sup>467</sup> became popular. The phagocytic cell then came to be regarded as only passively involved in resistance to infection. This view was strengthened when it was shown<sup>464</sup> that the enhanced phagocytosis of pneumococci previously exposed to serum resulted from the coating of the bacteria with antibody and complement. For many years phagocytosis was thought to depend on cell surface tension or charge effects<sup>404,431,450</sup> and to involve no expenditure of energy. This view was maintained even though it had been noted in 1933 that, during the phagocytosis of bacteria, leukocytes display an extra burst of oxygen consumption.<sup>400</sup>

The importance of the phagocytic cell itself to body defense was not reemphasized until the 1940's and later when Wood<sup>466</sup> showed that the outcome of infection was decided long before specific antibodies appeared in the serum. He demonstrated the ability of neutrophils to trap and ingest organisms in the absence of antibodies and serum factors and called the process "surface phagocytosis." It has since been shown that phagocytosis proceeds as well in a pure nitrogen atmosphere as in oxygen, that it is not inhibited by cyanide or dinitrophenol, and that inhibitors of glycolysis do inhibit phagocytosis.<sup>441,442</sup> It also has been found that a variety of enzymes and bactericidal activities reside in the neutrophil cytoplasmic granules and that these are discharged on phagocytosis.<sup>415,419,437</sup> Since the 1940's an understanding of chemotaxis, particle recognition and adsorption, opsonin activity, endocytosis, bacterial killing and digestion, and the proc-

Fig. 6-10A Schematic diagram of endocytosis, both phagocytosis of immunoglobulin-coated bacteria and pinocytosis are shown. The fusion of primary lysosome with the phagosome to form the digestive vacuole, the subsequent degradation of the bacteria leading to the formation of a residual body, and the expulsion of indigestible components are also depicted.

Fig. 6-10B Leukocyte metabolism as related to endocytosis and bacterial killing. 1, Glucose-6-phosphate dehydrogenase and 6 phosphogluconate dehydrogenase 2, NADPH oxidase 3, Glutathione reductase 4, NADPH linked lactic dehydrogenase 5, Glutathione peroxidase 6, Myeloperoxidase (MPO) 7, Phosphoglyceraldehyde dehydrogenase 8, NADH-linked lactic dehydrogenase 9, NADH oxidase (Modified from Klebanoff <sup>505</sup>)

esses associated therewith has accumulated with overwhelming rapidity. After years of controversy over the relative importance of these several factors it now appears that all are involved.<sup>468</sup>

### Chemotaxis<sup>435,447,458</sup>

Although the mobility of neutrophils and their concentration in inflammatory lesions were appreciated in the earliest experiments, the development of a two-compartment chamber with a membrane permeable to leukocytes separating the compartments has permitted easy quantitation of chemotaxis *in vitro* and has greatly facilitated investigation of chemotactic factors.<sup>401,405</sup> From such studies it is evident that both neutrophils and mononuclear phagocytes show directional migration under the influence of chemotactic agents, but a concentration gradient is needed for migration to occur. In the absence of a gradient, but with chemotactic factor present, random migration is enhanced and localization or "trapping" of the phagocytes occurs. Chemotaxis appears to be mediated by two means: *cytotaxins* which have a direct action on phagocytes (eg, casein, certain bacterial filtrates, and low molecular weight split-products of the complement components C5 and possibly C3, and a complex of C5, 6, 7) and *cytotaxigens* which are not chemotactic themselves but which generate chemotactic factor after interacting with serum, plasma, or components of complement. Examples of cytotaxigens are antigen-antibody complexes, endotoxin, certain bacteria, certain enzymes reacting with complement components, and lysosomes from neutrophils, macrophages, or liver. Certain cytotaxins appear to be specific for neutrophils (eg, culture filtrates of *E. coli*) while others such as casein induce migration of both neutrophils and monocytes.<sup>531</sup> In general, neutrophils are attracted by low molecular weight components.<sup>458</sup> The vasoactive amines, bradykinin, serotonin, and histamine have no chemotactic activity in the *in vitro* chamber.<sup>458</sup>

As yet only a few studies reveal the operation of chemotactic factors *in vivo*. In rabbit-

ear chamber experiments, random movement of leukocytes was seen in the center of injury, but preceding this a directional movement of leukocytes into the area was demonstrated.<sup>410</sup> The random movement is now suggested as reflecting the "trapping" of leukocytes in an area containing chemotactic factor but with no concentration gradient to provide direction.<sup>458</sup> In other studies a correlation between *in vitro* chemotactic activity generated by incubating minced rat tissue with serum and the *in vivo* accumulation of cells after injection of the activity was established.<sup>439</sup> However, a wide gap still exists between the significant role in inflammation that chemotaxis is recognized as playing and understanding of the mechanism by which it acts. The nature of receptors on the phagocytes is only beginning to be unraveled and we are ignorant of how, once recognized, the message is translated into directional locomotion.

### Particle Recognition and Adsorption

How phagocytes distinguish foreign particles and damaged autologous cells from normal self-components remains a mystery, but this capacity obviously is the essence of phagocytic function. Dog neutrophils have been shown to bind a specific type of IgG which enhances their phagocytic capacity for staphylococci in the absence of complement.<sup>432</sup> In other studies an alpha-1-glycoprotein capable of enhancing phagocytosis in the absence of complement was found in germ-free rat and guinea pig serum.<sup>426</sup> The presence of this activity in animals without prior exposure to foreign antigens suggests that it is not antibody and may be related to recognition and adsorption of foreign materials. However, how such factors enhance adsorption and phagocytosis is not clear.

It has been shown that neutrophils from guinea pig and sheep require divalent cations ( $\text{Ca}^{++}$  or  $\text{Mg}^{++}$ ) for adsorption and ingestion of particles,<sup>427</sup> and human leukocytes may require cations for attachment to a charged surface.<sup>419,409</sup> Presumably, in the absence of divalent cations, repulsive forces at the surfaces of the bacteria and the phagocytic cells

are sufficient to allow only a weak interaction.<sup>427</sup> In the absence of firm adsorption, bacteria are not ingested and can be washed off the cells.<sup>428</sup> However, from studies with macrophages it seems that divalent cations are needed not for particle adsorption but for the ingestion stage.<sup>432</sup> The osmolality of the medium is important also and high concentrations of glucose or salts may impair phagocytosis and leukocyte aggregation.<sup>413,444</sup> In certain tissues, such as the renal medulla, such factors may interfere with efficient phagocytosis.

*Opsonins*, long recognized as enhancing phagocytosis, act primarily on the particles rather than on the phagocytic cells, but the term has been applied in various ways since it was first used.<sup>406,452</sup> Opsonins include specific antibodies (heat stable), complement (heat labile), non-complement thermolabile factors, and perhaps other factors in the serum, such as lysozyme, which when adsorbed onto particles render them attractive to phagocytic cells. Clearer understanding of opsonin action is beginning to emerge as a result of the availability of procedures for fractionating immunoglobulins and complement into their several components. For example, in a study in rabbits of the *opsonin activity of antibodies* to *Proteus mirabilis* the IgG component was shown to enhance the uptake of living *Proteus* organisms (in the absence of complement) while the IgM fraction had little effect.<sup>456</sup> In other studies, in the guinea pig, 7S antibody was fractionated into two components,  $\gamma_1$  and  $\gamma_2$ . The  $\gamma_2$  antibodies attached to macrophages but the  $\gamma_1$  fraction did not, and neither fraction became attached to polymorphonuclear cells.<sup>403</sup>

Thus only certain immunoglobulin fractions appear to have cytophilic properties and these may be specific for only one cell type. The portion of the antibody that attached to the cell was on the Fc fragment and thus on the H chains of the molecule. In addition, there is evidence that *Staphylococcus aureus* contains a protein A substance which binds nonspecifically to the Fc portion of IgG and by this means blocks phagocytosis.<sup>425</sup> All of these investigations suggest that the Fab por-

tion of antibody reacts with organisms while the Fc portion contains cytophilic-binding sites. Thus immunoglobulins appear to facilitate contact between particles and those phagocytes with the necessary receptor sites. At present there is good evidence for such receptor sites on macrophages and polymorphonuclear cells.<sup>710</sup>

The opsonic activity of complement and other heat labile components of serum appears to be even more complex and is less well understood,<sup>406</sup> but the point to be made is that there are substances in normal serum that probably play an important role in promoting phagocytosis in the absence of specific antibody. Advancement in our understanding of foreign particle recognition and adsorption awaits elucidation of cell membrane structure, receptor sites thereon, and interactions with serum proteins, antibodies, and particle surfaces.

### Ingestion and Degranulation

The ingestion of particles by phagocytic cells requires the expenditure of energy<sup>441</sup> and is accompanied or immediately followed by a variety of complex biochemical events.<sup>460</sup> Although neutrophils contain a cytochrome system<sup>415</sup> and may use both aerobic and anaerobic mechanisms to produce energy, they utilize anaerobic glycolysis to support phagocytosis.<sup>454</sup> During ingestion the particle is surrounded by pseudopodia and the cell membrane invaginates to enclose and internalize it.<sup>453,494</sup> This is rapidly followed by a fusion of lysosome granules with the phagosome and the release of lysosomal contents, antibacterial substances and digestive enzymes into the phagocytic vacuole<sup>419,437</sup> (Fig. 6-10A). It will be recalled that there are two and perhaps three distinct types of neutrophil granules with different enzyme content (page 228). Since, after extensive phagocytosis, lysosomal granules are essentially absent the several types must all participate in the degranulation process. No migration of lysosomes from distant parts of the cell toward the phagosome has been recognized, but in neutrophils the contents of

specific granules are released into the phagosome first (leukocyte alkaline phosphatase was detected in phagosomes within 30 seconds) while the primary granule contents were found in the phagosome later (after one to three minutes).<sup>399</sup> The mechanism of phagosome-lysosome fusion is unknown, but it has been proposed that the continued interaction of complement and antibody within the phagosome releases lysolecithin which then acts on the lysosomal membrane to break it down. Fusion of phagosome and lysosome ensues.<sup>406</sup> The fragility of lysosomes at acid pH may also facilitate fusion.<sup>418</sup> After fusion, bacteria are usually quickly killed and the phagocytosed material is digested (see below).

A number of metabolic changes have been observed to occur during phagocytosis: there is a modest increase in glycolysis and lactate production and the pH within phagocytic vacuoles falls<sup>440,510,519</sup>; a two- to threefold increase in oxygen consumption occurs (which is resistant to cyanide and therefore does not involve mitochondrial cytochrome oxidation)<sup>454</sup>; consumption of the number one carbon atom of <sup>14</sup>C-labeled glucose and its conversion to CO<sub>2</sub> via the hexose monophosphate shunt increases six- to sevenfold<sup>515</sup> (also resistant to CN and other metabolic inhibitors); NADPH oxidation is increased fivefold, NADH oxidation is increased thirtyfold (pH 7.0),<sup>513</sup> and the dye, nitroblue tetrazolium (NBT), is reduced to blue formazan apparently by NADH oxidase<sup>482</sup>; formate oxidation is increased apparently by a peroxidase interacting with the increased amount of H<sub>2</sub>O<sub>2</sub> formed<sup>501</sup>; there is increased synthesis of membrane lipids<sup>429,492</sup>; and chloride and iodide ions are oxidized apparently via myeloperoxidase catalysis of the hydrogen peroxide generated.<sup>506</sup> Some of these reactions are illustrated in Figure 6-10B.

Since most of these events occur in the first several minutes after particle ingestion, the relation of one process to the others has been difficult to unravel.<sup>412</sup> However, the significance of these metabolic changes has become clearer since it was shown that neutrophils from patients with chronic granulomatous

disease (CGD) (see page 1326) do not exhibit the burst of oxygen uptake or glucose utilization via the hexose monophosphate shunt that normally occurs with phagocytosis.<sup>482,499</sup> Since particle ingestion and degranulation appear to be normal in CGD<sup>483,498,502</sup> but bacterial killing is not,<sup>498</sup> it should be possible to separate the metabolic events associated with each phase by comparing events in normal and in CGD neutrophils. From such studies it appears that increases in glycolysis and membrane lipid synthesis<sup>492</sup> are integral parts of the ingestion-degranulation process, while the other changes are involved with bacterial killing<sup>442</sup> even though they begin almost immediately after particle ingestion and before extensive degranulation has occurred.

### *Bacterial Killing and Digestion*<sup>503</sup>

Since bacterial killing decreases under anaerobic conditions whereas phagocytosis does not, it is thought that the "respiratory burst," mentioned earlier, is related to bactericidal activity. The nature of the events that take place has been surmised as the result of extensive investigations of the pathogenesis of chronic granulomatous disease (Chapter 42).

### *Metabolic Products*

The metabolic products of neutrophil metabolism that may have bactericidal action are lactic acid and H<sub>2</sub>O<sub>2</sub>. After particle ingestion the intraphagosomal pH has been reported to decrease to between 3.0 and 6.5.<sup>410,510,519</sup> It is known that some organisms such as pneumococci are sensitive to an acid pH while others tolerate acid environments without damage. In addition to a possible direct bactericidal effect the acid environment of the phagocytic vacuole may enhance the activity of lysosomal hydrolytic enzymes, most of which have optimal activity at acid pH. H<sub>2</sub>O<sub>2</sub> and superoxide formed during phagocytosis may have a direct bactericidal effect<sup>481,501</sup> and may also mediate other reactions (see below). It has been shown that anaerobic

conditions, phenylbutazone, catalase,<sup>505</sup> and hydrocortisone<sup>511</sup> decrease  $H_2O_2$  production and inhibit microbicidal activity, whereas the addition of  $H_2O_2$  to an anaerobic system partially restores the bactericidal effect.

### Nonenzymatic Agents

The nonenzymatic agents with antimicrobial activity include phagocytin, leukin, a group of cationic proteins, and lactoferrin. *Phagocytin*<sup>495-496</sup> was isolated from rabbit heterophils and shown to have antimicrobial activity that was optimal at acid pH, was temperature dependent, and was consumed during bactericidal activity. Another substance, *leukin*, was also isolated from rabbit cells and was shown to kill gram-negative organisms especially well at acid pH.<sup>520</sup> It is not yet clear whether phagocytin and leukin are different substances, but the latter appears to be clearly different from lysozyme and antibacterial histones.<sup>520</sup>

Leukocyte granules also contain a group of *cationic proteins* with differing bactericidal properties.<sup>523</sup> Some fractions are highly active against streptococci or staphylococci<sup>544</sup> while others are active against gram-negative organisms.<sup>523</sup> In rabbit heterophils these proteins appear to be located in the primary and secondary granules,<sup>485</sup> and are released after phagocytosis. In abscesses induced in rabbits and guinea pigs the causative organisms are coated by cationic protein at the time of microbial killing.<sup>521</sup>

*Lactoferrin* is still another bactericidal protein found in the specific granules of rabbit heterophils<sup>486</sup> and in human neutrophils<sup>536</sup> as well as in many secretions (milk, mucus, etc) and exudates.<sup>513</sup> Its strong chelating properties appear to account for its bactericidal effects and, in contrast to transferrin, this property is maintained at the low pH values encountered in exudates.

### Enzymatic Antimicrobial Activity

Neutrophil lysosomes contain a number of enzymes (see pages 228, 230) but only two of these, lysozyme and myeloperoxidase, have been shown to have microbicidal activity.

*Lysozyme* is a basic protein present in both primary and secondary neutrophil granules and is capable of hydrolyzing the cell wall of certain bacteria, thus effecting their death. Although the number of organisms susceptible to the direct action of lysozyme is small, some are made sensitive to its action after exposure to antibody and complement or to  $H_2O_2$  and ascorbic acid.<sup>505</sup> Usually bacterial death appears to precede the action of lysozyme and thus its action may be mostly digestive. The leukocytes of Guernsey and Hereford cattle contain no lysozyme but kill organisms normally.<sup>517</sup>

*Myeloperoxidase* (MPO) is present in high concentration in the azurophilic, primary granules of neutrophils and is released into the phagosome during granule lysis.<sup>505</sup> MPO has bactericidal, fungicidal, and viricidal activity<sup>505</sup> which is thought to depend on the oxidation and fixation of chloride, bromide, or iodide, a process which is mediated by MPO and the hydrogen peroxide generated during phagocytosis.<sup>504,506</sup> In addition to halides, thyroxine or triiodothyronine may act as a cofactor in this reaction. It is known that leukocytes concentrate iodide, thyroxine, and triiodothyronine, and an accelerated turnover of the latter two compounds occurs during bacterial infection.<sup>505</sup> Since azide inhibition of MPO greatly decreases microbicidal activity of normal leukocytes, the MPO system appears to be an important defense mechanism.<sup>501</sup> However, in patients with MPO deficiency the activity of non-MPO-dependent systems appears to be increased, thus partially compensating for the MPO deficiency.<sup>504</sup> This may explain the finding of increased susceptibility to infection in only one of five MPO-deficient patients.<sup>508</sup>

Phagocytosis is not always successful in killing bacteria, however. Some organisms (eg, certain virulent staphylococci) may survive and multiply within neutrophils and appear to kill them, thus overcoming the defense mechanism.<sup>544</sup> Still other materials ingested by neutrophils, such as the uric acid crystals of gout or the hydroxy apatite crystals of pseudogout, may cause breakdown of the phagosome wall and release the hydro-

lytic enzymes into the cell sap.<sup>522</sup> This is fatal to the cell; it then lyses and releases its enzymes into the surrounding tissues where they cause tissue damage and secondary inflammation. In certain streptococcal and other infections, bacterial exotoxins (eg, streptolysin) are released and damage the phagosomal membrane, thus killing the cell in a similar manner<sup>523</sup>; the infecting organism is freed in the process. Also certain vitamins (vitamin A) and drugs are incorporated into phagosomal membranes and render them fragile and readily susceptible to rupture, thereby leading to inflammation.<sup>522</sup>

*Digestion of bacteria* is demonstrated both by changes in the morphologic appearance of phagocytosed organisms and by the release of labeled fragments of bacteria into the surrounding medium.<sup>489,523</sup> Digestion is thought to result from the action of the acid hydrolytic enzymes released into the phagosome from the primary lysosome. Metabolic blocking agents such as iodoacetate, cyanide, and arsenite, which inhibit glycolysis and respiration, had no effect on digestion once the bacteria were within the cell.<sup>490</sup> The rate of digestion was different for RNA, lipids, DNA and protein, and immune sera delayed the digestion of coated bacteria. Some bacteria ingested by neutrophils may be killed and digested slowly (eg, certain pneumococci), the undigested material remaining as myelin or residual bodies.

### Secretory Functions of the Neutrophil

In addition to the fact that the contents of the neutrophil are released passively, as a result of cell lysis, there is evidence that a variety of substances are actively secreted by leukocytes in vitro.<sup>548</sup> These substances have been shown to originate from the granule fraction and include ribonuclease, deoxyribonuclease, betagluconidase, hyaluronidase, phagocytin, lysozyme, and histamine.<sup>548</sup> Recently, vitamin B<sub>12</sub>-binding  $\alpha$ -globulin<sup>532</sup> and leukocyte pyrogen<sup>545</sup> have been added to the list of secretory products. Since some of these substances are present in plasma normally and the concentration increases in pa-

tients with diseases involving the neutrophil system,<sup>530,550</sup> it has been suggested that neutrophils may serve a secretory function in vivo as well as a phagocytic role.<sup>532,548</sup>

Best studied is the  $\alpha_1$ B<sub>12</sub>-binding protein, *transcobalamin I*.<sup>532,547</sup> This is thought to function as a storage protein for vitamin B<sub>12</sub> and is a poor source of metabolically available vitamin<sup>538</sup> (see also Chapter 4, page 139). Markedly elevated transcobalamin I levels are seen in chronic myelocytic leukemia and in myeloid metaplasia; low values occur in chronic leukopenia and aplastic anemia<sup>538</sup>, and good correlation with blood granulocyte pool size has been reported.<sup>530</sup> These findings support the hypothesis that transcobalamin I is a secretory product of neutrophils and that the amount produced is related to the total neutrophil mass.

Another substance present in both primary and secondary neutrophil granules is *lysozyme*; it is also present in monocytes, serum, and tears and other secretions.<sup>542</sup> Increased concentrations in serum and urine are found in association with monocytic and myeloblastic leukemias.<sup>542,550</sup> It has been proposed that lysozyme is released from neutrophils when they are destroyed and that serum lysozyme may provide a measure of granulocyte turnover rate.<sup>534</sup> However, reasoning by analogy with the B<sub>12</sub>-binding protein and from the lack of correlation of granulocyte turnover rate with serum lysozyme levels in neutropenic patients,<sup>550</sup> it seems at least as likely that lysozyme is produced by both neutrophils and monocytes and may be either secreted by the intact cells or is released from them when they are destroyed.

In an in vitro system, *endogenous pyrogen* is produced by a variety of mammalian neutrophils and monocytes, including those of man.<sup>549</sup> Pyrogen production is activated by the phagocytosis of bacteria or after exposing the cells to endotoxin, or, in the case of human cells, to etiocholanolone. The process is temperature dependent and appears to require transcription of messenger RNA and its translation by ribosomes into new protein synthesis.<sup>540</sup> Leukocyte pyrogen cannot be released from blood leukocytes unless they

have been activated and a three- to four-hour latent period has elapsed; the amount produced is related to the degree of phagocytosis.<sup>545</sup> Leukocyte pyrogen has been detected in the serum of animals after endotoxin injection and thus the secretory process appears to be operative *in vivo* as well as *in vitro*.

### Eosinophil Series—Kinetics, Properties, and Functions

The distinctive morphologic appearance of eosinophils and the fact that these cells tend to appear at sites of foreign protein and parasite deposition and in association with allergic reactions have resulted in an enormous body of literature. However, understanding of the production, turnover, and function of eosinophils is limited. This is due in part to the fact that eosinophils constitute only a small proportion of marrow and blood leukocytes in normal man (Tables 2-1 and 6-4) and animals and thus quantitative studies are difficult to carry out. The available data are limited largely to studies in laboratory animals.<sup>601,603,611,651,676,677</sup>

The production of eosinophils, as well as that of neutrophils, occurs only in the bone marrow in normal man. Some eosinophil production has been reported to occur in the spleen of rodents,<sup>611,642</sup> but it now seems that only maturation occurs there.<sup>677</sup> Marrow eosinophilic promyelocytes and myelocytes are capable of mitosis (mitotic index < 2%)<sup>601,676</sup>; the metamyelocytes and more mature forms are usually regarded as post-mitotic stages undergoing maturation.<sup>611,651</sup> The flow of cells through the system is considered to follow a pipeline pattern as with neutrophils and there is a substantial marrow reserve of mature cells which can be mobilized on demand.<sup>611,642,651,676,677</sup>

#### *Production and Turnover in the Bone Marrow*

After the parenteral injection of tritiated thymidine into rodents, only the promyelocyte and myelocyte eosinophils were labeled initially.<sup>627,676</sup> The labeling indices appeared

to be somewhat higher than in the neutrophil series and label appeared in nondividing marrow eosinophils within four hours.<sup>627</sup> The mean myelocyte turnover time in rats has been estimated to be 40 hours to three days<sup>620,627</sup> and the total marrow transit time is reported as 5.5 days.<sup>676</sup> The minimal transit time from labeling with DNA precursors to appearance of labeled cells in the blood, the *emergence time*, has varied somewhat from species to species but is about 36 hours in mice,<sup>603,622,640</sup> 24 to 67 hours in rats,<sup>603,604,620,627,642,677</sup> and 60 hours in guinea pigs. When comparisons between neutrophils and eosinophils have been made the emergence time for eosinophils has been 20 to 24 hours shorter than that for neutrophils.<sup>622,640</sup> The mean transit time from myelocyte labeling in the marrow to peak radioactivity in the blood was about three to four days in animals. Detailed measurements of cell cycle kinetics for the eosinophil series in the rat have been reported, as well as measurements of eosinophil marrow mass.<sup>601</sup> In the guinea pig, it was estimated that there are 300 to 400 marrow eosinophils for each eosinophil in the blood with relative compartment sizes as follows: early forms, 50; metamyelocytes, 50; band and segmented forms in the bone marrow, 300; and circulating eosinophils, 1.<sup>651</sup> In the rat, in one study<sup>676</sup> only 10% of eosinophils were mature forms, while, in another,<sup>601</sup> two thirds of marrow eosinophils were nondividing.

In the only data for man, the maturation and emergence time of eosinophils was shorter than that for neutrophils, and DNA synthesis time was about the same as for neutrophils.<sup>679</sup> Kinetic studies in patients with eosinophilia suggest a pattern similar to that of neutrophils with a three- to four-day emergence time and a nine-day mean transit time.<sup>649</sup>

#### *Eosinophil Kinetics in the Blood*

In animals, the blood turnover time has been estimated to be less than 24 to 35 hours.<sup>603,620</sup> After continuous infusion of <sup>3</sup>HTdR into rats, heavily labeled eosinophils

left the blood to enter the tissues in a random fashion with a  $t_{1/2}$  of 8 to 12 hours.<sup>612</sup> After a single pulse label, a  $t_{1/2}$  of 6.7 hours and exponential disappearance were observed.<sup>617</sup> In man, random disappearance of blood eosinophils has also been reported,<sup>679</sup> and, in one patient with eosinophilia, radiochromate-labeled eosinophils left the blood exponentially with a  $t_{1/2}$  of about five hours.<sup>649</sup> It has been suggested that eosinophils may return to the blood,<sup>649</sup> but the evidence for this is not very convincing.

The fate of eosinophils is no better understood than is that of the neutrophil. Eosinophils are found in saliva in man<sup>679</sup>; in rodents, large numbers are present in the gastrointestinal tract in which site they survive less than six days.<sup>642</sup>

#### Effect of Adrenal Steroids and ACTH on Eosinophil Kinetics<sup>604,609,650</sup>

Adrenal steroids and ACTH produce eosinopenia in man<sup>681</sup> and suppress foreign protein-induced eosinophilia in animals.<sup>609,650</sup> The means whereby these effects are accomplished are uncertain. Lysis of eosinophils would not seem to be a satisfactory explanation since adrenal steroids do not lyse eosinophils *in vitro*<sup>609</sup> or in the bone marrow or tissues of animals given steroids.<sup>604,616</sup> Steroid eosinopenia occurs within two to three hours; consequently cessation of marrow eosinophil release as the sole explanation does not seem plausible if the estimates of blood eosinophil survival time given above (5 to 24 hours) are approximately correct. Isotopic studies suggest that a single injection of steroid produces reversible sequestration of eosinophils, presumably in the reticuloendothelial system,<sup>604,616</sup> while continuous steroid administration appears to interfere with marrow eosinophil release.<sup>604</sup> No mechanism for acute sequestration has been offered.<sup>611,651</sup> Since the blood eosinophil concentration increases after chronic infusions of histamine<sup>610</sup> or after the administration of histamine-releasing drugs,<sup>707</sup> and since histamine is reported to be chemotactic for eosinophils,<sup>610</sup> it has been suggested

that histamine may normally stimulate eosinophil release and/or production.<sup>609,611,650,651</sup> Chronic steroid administration might then affect the system by suppressing histamine release perhaps by stabilizing basophil and mast cell lysosomal membranes, by interfering with histamine biogenesis,<sup>647</sup> or by still other poorly defined mechanisms.<sup>650</sup>

#### Control Mechanisms

Since bacterial infections and certain other inflammatory events induce neutrophilia and, usually, eosinopenia, while antigen-antibody reactions and certain foreign proteins cause eosinophilia, separate control mechanisms for the two cell systems are suggested. This concept is supported by reports of an eosinophil-releasing factor<sup>677</sup> and a diffusible factor capable of stimulating eosinophil production by blasts and promyelocytes in millipore chambers implanted in the peritoneal cavity of mice.<sup>653</sup>

#### Normal Values and Physiologic Variations

In man, the normal concentration of eosinophils in the blood is less than  $0.7 \times 10^9$  cells/l (Table 6-4) and the mean value is  $0.15 \times 10^9$  cells/l as determined from the total leukocyte count (electronic counter) and the differential count. Direct measurements of absolute numbers of eosinophils<sup>611,674</sup> gave very similar normal values in some studies (mean  $0.159 \times 10^9$  cells/l, limits 0.054 to  $0.465^{615,682}$ ), but somewhat lower figures (mean values less than  $0.05 \times 10^9$  cells/l and upper limits less than about  $0.11 \times 10^9$ /l) in others.<sup>656</sup> Diurnal variation in the eosinophil count with high values late at night and low values at noon have been reported by some workers,<sup>615,639,682</sup> but others found no pattern common to all subjects.<sup>600</sup> Emotional stress may be associated with a decrease in total eosinophil concentration,<sup>653</sup> while exercise produces a transient increase.<sup>637</sup> Fluctuation in eosinophil count during the menstrual cycle has been reported, but the results have been variable and discrepant.<sup>637,665</sup>

### Properties and Functions

That eosinophils take part in the response to foreign protein has been recognized since the institution of antiserum therapy in the early 1900's and the production soon thereafter of allergic reactions in animals. It has also been evident that the eosinophilic response occurs in previously sensitized animals as a result of reactions associated with the interaction of antigen and antibody.<sup>659</sup> The search for substances chemotactic for eosinophils has been pursued extensively in the hope that some understanding of eosinophil function could be derived therefrom. With immunofluorescent labeling methods it was demonstrated that injected soluble or insoluble antigen-antibody complexes attract eosinophils and are phagocytized by them,<sup>663</sup> but excess antigen or antibody does not produce these effects.<sup>660</sup> A localized eosinophilia develops within 24 hours of the application of pollen extract to pollen-sensitive individuals but does not occur in normal subjects.<sup>644</sup> This reaction can be diminished by a series of desensitizing injections, presumably as a result of the formation of new incomplete or blocking antibodies which may interfere with the interaction of antigen and receptor sites on sensitized cells.<sup>646</sup> Other studies in which several types of antigen-antibody complexes or protein aggregates were injected into animals suggest that eosinophils may be attracted to substances with a particular molecular configuration.<sup>632,633</sup> A variety of other materials, many of them proteolytic enzymes, and even inert materials such as asbestos have induced eosinophilia when injected intraperitoneally into mice<sup>623</sup>; it has been suggested that they do so by activating the coagulation mechanism to produce fibrin.<sup>667</sup> It has been demonstrated that fibrin or proteolytic enzymes that promote fibrin production are chemotactic for eosinophils and that eosinophils contain profibrinolysin in their granules.<sup>667</sup> There also is evidence that basophils and tissue mast cells from sensitized subjects release their histamine when exposed to the sensitizing antigen.<sup>670</sup> The reported eosinophilotactic prop-

erties of histamine were mentioned above; it has been suggested that one function of eosinophils is to destroy histamine.<sup>611,651</sup> An extract of eosinophils has been shown to reduce the edema produced by the injection of histamine, 5-hydroxytryptamine, or bradykinin and it appears that an important function of eosinophils is to limit the effects of some of the biochemical mediators.<sup>611</sup>

Since all of the above-mentioned studies involved intact animals it is impossible to evaluate adequately the chemotactic properties of the substances employed. However, the demonstration that sensitized lymphocytes interact with appropriate antigen and produce a variety of soluble substances, such as migration inhibition factor, cytotoxins, and chemotactic factors,<sup>635</sup> suggests that the mobilization of eosinophils may be mediated by similar indirect means.<sup>618</sup> It has been shown that the reaction of immune complexes with the complement system produces a trimolecular complex,  $C_5,6,7$ , and several other substances that are chemotactic for both eosinophils and neutrophils.<sup>684</sup> These substances include soluble factors in bacterial culture filtrates and reaction products of serum and either immune complexes or plasminogen.<sup>684</sup> In addition, a substance selectively chemotactic for eosinophils has been found.<sup>628</sup> Only complexes that can fix complement (IgG or IgM, but probably not IgA or IgE) appear capable of generating chemotactic factor.<sup>657</sup> The fact that IgG<sub>1</sub> mediates the eosinophil-rich anaphylactic reaction while IgG<sub>2</sub> mediates the neutrophil-rich Arthus reaction<sup>661</sup> suggests that different cell receptor sites may play a role in chemotaxis and in phagocytosis of opsonized particles.

In addition to observations of eosinophil reactions after a second exposure to antigen, as discussed above, there is evidence that eosinophils may be involved very early in the immune response; they are phagocytic for antigen<sup>639</sup> and have been shown to accumulate in local lymph nodes within several hours after injection of antigen<sup>632,633</sup> and before antibody could be present.

No clear secretory function of eosinophils has been established. *Charcot-Leyden* crystals

form at sites of eosinophil or basophil concentration. These appear to be protein in nature and come from the cell cytoplasm rather than the contents of the granules.<sup>606</sup> This crystal formation does not seem to be the result of secretory phenomena.

The enzymes contained in eosinophil granules are similar to those in neutrophils except that eosinophils have a high content of peroxidase and aryl sulfatase and contain no lysozyme or phagocytin.<sup>607</sup> The absence of these antimicrobial substances has been taken to indicate that bacterial killing is not a major function of eosinophils.<sup>607</sup> However, a comparison of phagocytosis by eosinophils and neutrophils from human subjects demonstrates essentially similar processes in the two cell forms.<sup>625</sup> Eosinophils ingest bacteria, polystyrene particles, or fungi, but a smaller percentage of eosinophils than neutrophils participates and the eosinophils do so less avidly than do the neutrophils; eosinophils did not ingest antibody-coated red cells. Degranulation occurs<sup>607,625</sup> and the metabolic events associated with phagocytosis are similar to those observed in neutrophils.<sup>625</sup> However, more pronounced production of peroxide has been found in eosinophils than in neutrophils, apparently as the result of the high concentration of NADPH oxidase in eosinophil granules. In contrast, neutrophils derive  $H_2O_2$  through cytoplasmic NADH. Nevertheless, in spite of the enhanced peroxide generation, eosinophils were less effective in killing bacteria than neutrophils.<sup>613</sup>

#### Basophil Series—Kinetics, Properties, and Functions

The physiology, kinetics, and functions of basophils, the least numerous of the blood leukocytes in man, are poorly understood. Soon after their description by Ehrlich in 1891, basophils were recognized as probably being different from the tissue mast cells, which had been described some 14 years earlier, in spite of their obviously similar staining characteristics.<sup>718</sup> The basophil is smaller and usually less granular than the mast cell, and it has a bi- or tri-lobed nucleus

while the mast cell is mononuclear. Other morphologic and biochemical differences and similarities are cited on pages 232, 233.

#### Kinetics

Basophils are thought to be produced in the bone marrow in a manner similar to that of the production of neutrophils and eosinophils.<sup>724</sup> When tritiated thymidine was given to human subjects the initial labeling indices for eosinophilic and basophilic myelocytes in the bone marrow were similar to those for neutrophilic myelocytes.<sup>721</sup> The kinetics of eosinophils and of basophils in the marrow also were similar to one another and to those of the neutrophil system; there was a three-hour lag period after tritiated thymidine injection before label was seen in metamyelocytes; a one-day lag period before labeled band forms were seen; and a 1.5-day period before label was present in segmented basophils in the bone marrow. The "emergence time" from tritiated thymidine injection to the appearance of labeled basophils in the blood was 2.5 days and peak values for percent labeled basophils (about 23%) were reached on day 7.<sup>721</sup> The sequential flow of label through the several stages of maturation in the marrow and into the blood appeared entirely compatible with the pipeline scheme already described for neutrophils (page 244, Fig. 6-8).

Because of the paucity of basophils in the blood, no studies of pool sizes, cell distribution, or half-disappearance time have been possible. As with other granulocytes the fate of basophils is unknown. Although they may migrate into the tissues, there is no evidence that they transform into tissue mast cells. In fact, *mast cells* have been thought to be derived from connective tissue cells, and the finding that less than 0.05% were labeled after tritiated thymidine injection into mice suggests that the mast cell population turns over very slowly; the estimated turnover time is 9 to 18 months.<sup>737</sup> Other studies demonstrated that, after degranulation *in vivo* with the drug, 48/80, rat mast cells quickly reappeared and their granules were heavily la-

beled with administered radiosulfate.<sup>738</sup> Although this would support the earlier concept that mast cells are derived from nongranular precursor cells fixed in the connective tissues and that they release their granules on appropriate provocation and can replenish them rapidly,<sup>707</sup> subsequent studies demonstrated that after tissue mast cell degranulation *in vivo*, the tritiated thymidine labeling index increased from a control level of 0.06% to a maximum value of 4.5% two days after degranulation.<sup>727</sup> These results were considered to indicate that the connective tissue mast cells, though usually a very stable cell population, can be stimulated to divide. An equally plausible explanation, however, is that new cells were directed into the system from some precursor pool, perhaps blood monocytes.<sup>732</sup> This suggestion is based on the finding that, in the rabbit, antimacrophage serum (but not antilymphocyte serum) produced mast cell degranulation and karyolysis; by the third day thereafter, mononuclear cells containing metachromatic ("mast cell") granules reappeared, and the same cells also contained granules which stained with naphthol AS-D chloroacetate esterase, a stain which is thought to be specific for granules present only in cells of the monocyte-macrophage system.<sup>712</sup>

### *Physiologic Variations*

The development of methods for direct enumeration of basophils<sup>720,731</sup> has made possible a number of studies of variations in the concentration of basophils in the blood. In newborn infants, basophils are relatively numerous but decrease to normal adult levels ( $0.042 \times 10^3$  cells/ $1 \pm 0.048$  [2 SD]<sup>726</sup>) by the fifth postpartum day.<sup>719</sup> Basophils have the same diurnal rhythm as eosinophils, the highest blood concentration occurring during the night and the lowest in the morning.<sup>703,722</sup> No fluctuation during the day is associated with meals or moderate exercise has been noted.<sup>726</sup> In women the blood basophil concentration may fluctuate during the menstrual cycle, highest values occurring at the onset of menstrual bleeding; a drop in

basophil count has been associated with ovulation in humans and rabbits.<sup>734</sup> In rabbits, basophils accumulate in the ovaries and fallopian tubes at the time of ovulation. It has also been shown that steroid hormones cause a parallel decrease in basophil and eosinophil concentration in the blood, and a common influence of the pituitary-adrenal system on both cell lines has been postulated.

### *Properties and Functions*

The blood basophils have been shown to be capable of sluggish motility,<sup>4</sup> they have been noted to migrate into the skin or peritoneum after injection of foreign protein,<sup>740</sup> and they accumulate in skin windows in sensitized individuals.<sup>740</sup> Although basophils are capable of phagocytosis<sup>728</sup> it is not clear that this is their major function. Basophils and tissue mast cells also release their granule contents outside the cell (exocytosis) after exposure to a variety of stimuli such as mechanical irritation and, in sensitized subjects, to antigen<sup>701,715,740</sup> or cold.<sup>718</sup> Thus they appear to have a major secretory function.

The high content of histamine in basophils as compared with other blood leukocytes has been demonstrated repeatedly.<sup>708,728,735</sup> The histamine is contained within the basophil granules in amounts ranging from 1 to 2.4  $\mu\text{g}$  per  $10^6$  cells.<sup>708,728</sup> However, rat mast cells contain 40  $\mu\text{g}/10^6$  cells,<sup>728</sup> and since they are more numerous than basophils in the body, it is likely that only a minor fraction of total body histamine is present in basophils.<sup>728</sup> Human basophils contain histidine decarboxylase and thus can synthesize histamine.<sup>709</sup>

With anti-IgE antibody it has been shown that the Fc portion of IgE (reaginic antibody) is bound by specific receptor sites on human basophils.<sup>710,711</sup> The reaction of basophils with anti-IgE results in degranulation and the release of histamine *in vitro*, while injection into the skin produces erythematous wheal reactions.<sup>711,712</sup> Calcium and magnesium ions are necessary for degranulation and histamine release. A noncomplement component of serum, though not necessary for the reaction,

enhances it by increasing the amount of histamine released.<sup>711,712</sup> IgE is found on basophils of both normal and atopic individuals,<sup>711</sup> and contact with allergens results in degranulation.

Heparin also has been demonstrated in the granules of basophils and mast cells.<sup>700,709</sup> In addition to their involvement in hypersensitivity reactions, basophils appear to release heparin during postprandial lipemia,<sup>730</sup> and a correlation between the blood basophil concentration and plasma triglyceride level was reported.<sup>704</sup> It is believed that basophils facilitate triglyceride metabolism by releasing heparin, which in turn activates lipoprotein lipase.<sup>704</sup>

### Monocyte Series—The Mononuclear Phagocyte System—Kinetics, Properties, and Functions

#### Site of Production and Kinetics

Within the last decade the transfusion of allogeneic marrow cells into irradiated, recipient mice to produce chimeras has clearly established the bone marrow as the source of

monocytes and macrophages.<sup>92,108,133</sup> The transfusion of <sup>3</sup>HTdR-labeled, syngeneic marrow cells into irradiated rats has confirmed these findings,<sup>136</sup> and similar studies have shown that thoracic duct lymphocytes or cell suspensions from lymph nodes or thymus cannot serve as sources of macrophage precursors; spleen cells could, but they were not a major source.<sup>130,136</sup> After 24 hours of incubation with <sup>3</sup>HTdR, one third of marrow mononuclear phagocytes were labeled as compared with 2.2% in peritoneal macrophages and no uptake by blood monocytes.<sup>130</sup> These findings suggest that the marrow contains a proliferating population that supplies monocytes to the blood which in turn enter the tissues and become macrophages (Fig. 6-11).

#### Promonocytes

More detailed marrow incubation studies have revealed that a group of younger-appearing forms, larger in size than monocytes and with deeply basophilic cytoplasm, are heavily labeled after incubation with <sup>3</sup>HTdR as compared with no uptake of label

Fig. 6-11. Model of the production and kinetics of the monocyte-macrophage system in the mouse. The marrow and blood compartments are drawn to show their relative size. The compartment transit times are derived from <sup>3</sup>HTdR-labeling studies.<sup>177</sup> The curved, solid arrow emphasizes the rapid appearance of labeled monocytes in the blood after <sup>3</sup>HTdR injection and the apparent lack of a pipeline flow of cells through the system. The interrupted arrow denotes the possible return of avidly phagocytic macrophages from the tissues to the blood.

by typical marrow monocytes.<sup>777</sup> These younger, proliferating forms were termed "promonocytes." They were distinguished from monocytes and macrophages by hyperdiploid content of DNA in the majority,<sup>777</sup> and by morphologic and staining differences.<sup>778</sup> Promonocytes constitute about 15% of the mononuclear phagocytes in mouse marrow, but in human marrow only 2.9% of marrow cells were identified as promonocytes.<sup>759a</sup>

After the injection of <sup>3</sup>HTdR intravenously into mice, 70% of marrow promonocytes were labeled initially while marrow monocytes were essentially unlabeled. Subsequently this pattern changed. The promonocyte-labeling index remained almost constant during the next 24 hours while the marrow and blood monocyte-labeling indexes increased in an identical fashion.<sup>777</sup> The promonocyte grain count decreased while the grain count in marrow and blood monocytes remained constant at about one half that of the promonocytes during the first six hours of the study. Since monocytes do not divide, this suggests that they are derived from promonocytes after one division and that some rapidly enter the blood while others remain in the marrow (Fig. 6-11).

In normal man, only 12% of marrow promonocytes were labeled after incubation *in vitro* (<sup>3</sup>HTdR. Double-labeling studies *in vitro* (<sup>3</sup>HTdR and <sup>14</sup>CTdR) as well as serial <sup>3</sup>HTdR injections gave a mean DNA synthesis time of about 10 hours and a generation time of about 29 hours for promonocytes.<sup>759a</sup> From studies of blood monocyte labeling after intravenous injection of <sup>3</sup>HDFP the marrow proliferation pool transit time was estimated to be about 55 hours. This figure is about twice the monocyte generation time and suggests that there are two catenated promonocyte generations in man.<sup>759a</sup> After <sup>3</sup>HTdR injection, labeled monocytes appeared in the blood within five to seven hours, thus demonstrating an absence of a significant storage compartment.<sup>759a</sup>

A precursor of the promonocyte has not been identified; however, the ability of gran-

ulocytic colonies grown in agar or from the spleen to transform into macrophage colonies<sup>759,783</sup> suggests that early myeloid forms may differentiate along this as well as the granulocytic route (see also Chapter 2 and Fig. 2-6, page 52).

### Production in the Mitotic Compartment<sup>777</sup>

From the increase in promonocyte labeling index (LI) observed during studies in which <sup>3</sup>HTdR was injected every two hours into mice, the rate of promonocyte entry into DNA synthesis was found to be 5.15% per hour.<sup>777</sup> From this and the initial LI of 69.8% the average DNA synthetic time ( $t_s$ ) was calculated to be 13.6 hours ( $69.8/5.15 = 13.6$ ). The mean promonocyte generation time ( $t_g$ ) as calculated from  $t_s$  and LI ( $t_g = t_s/LI$ ) was 19.5 hours.<sup>777</sup> Very similar values for  $t_s$  and  $t_g$  have been reported for the rat.<sup>785</sup> From the size of the marrow promonocyte pool (see below) and  $t_g$  the daily production of monocytes can be calculated to be  $0.49 \times 10^6$  cells/day in mice.

The *promonocyte-monocyte population size of mouse marrow* as determined from measurements of total femur cellularity and differential cell counts was  $2.4 \times 10^6$  cells ( $0.4 \times 10^6$  promonocytes and  $2.0 \times 10^6$  monocytes). From this one might infer that there is a marrow monocyte reserve similar to the marrow neutrophil reserve. However, a comparison of the increase in percent of labeled monocytes in blood and marrow after <sup>3</sup>HTdR injection showed little delay (less than two hours in mice and less than eight hours in the rat) in the appearance of labeled monocytes in the blood.<sup>730,777,785</sup> These observations together with a marrow monocyte turnover rate of only 1.5% per hour suggest that monocytes do not mature and leave the marrow according to a pipeline pattern. Rather, some cells appear to leave the marrow soon after production (perhaps in a random fashion) while others may remain in the marrow for several days (Fig. 6-11).

Monocyte production can also be calculated from the turnover of blood monocytes

heavily labeled with  $^3\text{HTdR}$  during their formation. From the half-disappearance time of 22 hours<sup>130</sup> and a blood monocyte pool calculated (from the blood volume and absolute monocyte concentration) to be  $1 \times 10^6$  cells,<sup>177</sup> effective monocyte production in the mouse is calculated to be about  $0.3 \times 10^6$  cells/day.<sup>177</sup> This value is somewhat less than that determined from LI data (see above).

It has been estimated that in normal man the marrow promonocyte pool is about  $600 \times 10^6$  promonocytes per kilogram of body weight.<sup>759a</sup> From this, the labeling index and the DNA synthesis time (see above) the normal monocyte birth rate is calculated to be about  $7.0 \times 10^6$  monocytes/kg/day.<sup>759a</sup>

### Monocyte Kinetics in the Blood

The blood monocytes are a population of recently formed young cells on their way from the bone marrow to their ultimate sites of activity in the tissues. Labeled monocytes from the marrow enter the blood at a rate of 1.7%/hour in normal mice. The disappearance of heavily labeled cells from the blood follows an exponential curve with a  $t_{1/2}$  of 22 hours.<sup>130</sup> Somewhat longer  $t_{1/2}$  values (48 hours) have been reported in rats, and since the disappearance of label did not follow a single exponential it was suggested that the cells or the label recirculates.<sup>783</sup>

By labeling autologous blood with  $^3\text{HDFP}$ , reinjecting the labeled cells, and measuring the proportion of labeled cells present at later times by autoradiographic techniques, blood monocyte kinetics have been evaluated in man.<sup>759a</sup> In these studies the marginal monocyte pool was found to be about 3.5 times the size of the circulating pool. Blood monocytes left the vascular system in an exponential manner with a  $t_{1/2}$  of 8.4 hours (4.5 to 10 hours). From the blood pool size and the  $t_{1/2}$  the blood monocyte turnover rate was calculated to be about  $168 \times 10^6$  cells/kg per day. This figure is in very good agreement with the  $^3\text{HTdR}$  data described above.<sup>759a</sup>

Alterations in monocyte kinetics have been observed after the administration of adrenal

steroids to humans<sup>750</sup> and mice.<sup>775</sup> Profound monocytopenia develops promptly in both species and its duration and degree depend on the amount, solubility, and route of steroid administration. In man the cellularity of induced exudates was decreased by steroid administration.<sup>750</sup> In mice the number of cells harvested from the peritoneum was only moderately decreased (about 30%), but the flow of thymidine-labeled monocytes from the blood into the peritoneum in response to an inflammatory stimulus was markedly reduced. The mechanism of the sudden monocytopenia is not understood, nor is it clear whether the reduced cellularity at the site of inflammation merely reflects the monocytopenia or is the result of other steroid effects on the monocytes or the vascular wall or is due to yet other factors.

In septicemia there was enhanced monocytopenia in the marrow and the blood monocyte turnover rate was increased.<sup>759a</sup>

### Tissue Macrophages

The evidence that tissue macrophages are derived from blood monocytes which in turn come from marrow was cited above (page 267). After leaving the blood and entering various tissue sites, monocytes transform into macrophages and become avidly phagocytic.<sup>102,107,122,127,737</sup> Macrophages have traditionally been divided into "fixed" and "wandering" forms. The "fixed" macrophages take on a stellate or fusiform appearance as they stretch out along bundles of collagen or reticular fibers, and it may be difficult to distinguish them from fibroblasts by light microscopy. However, with the electron microscope, differentiation appears feasible and is made possible by the prominent rough endoplasmic reticulum of reticular cells, differences in mitochondria, and the presence of dense material (presumably tropocollagen), in contrast to the sparse rough endoplasmic reticulum and the prominent lysosome formation of fixed macrophages.<sup>770</sup> Some confusion has arisen because fibrocytes are phagocytic and take up vital dyes or metal particles, although to a consid-

erably lesser extent than do macrophages. However, fibroblasts do not come from monocytes; rather they appear to arise from connective tissue cells in the tissues surrounding an area of injury.<sup>770,771</sup> In sites such as connective tissue, spleen, liver, or lymph nodes, "fixed" macrophages are abundant and in normal tissues most macrophages appear to be of the sessile, inactive, fixed type. When stimulated by inflammation, some withdraw their dendritic processes and become actively motile, "free," or "wandering" macrophages, while others may enter DNA synthesis and divide or undergo other changes (see below). Thus classification as "fixed" and "wandering" macrophages appears to have little real functional significance except that the site of fixation may influence subsequent differentiation and function. For example, spleen or liver macrophages are exposed to the blood and appear to be responsible for clearing it of foreign materials and effete cells, while alveolar or lymph node macrophages, because of their locations, have somewhat different functions.

The number of tissue macrophages far exceeds the circulating monocyte pool, but a valid figure cannot be given. Estimates of the size of the macrophage pool in the spleen, liver, and bone marrow of rats suggest that there are about one billion cells in each location. Similar calculations indicate that in man there are 200 billion macrophages (RE cells) in the spleen, the liver, and the bone marrow (see Chapter 8, page 352). Thus there are at least 50 times as many macrophages in the spleen, liver, and bone marrow of man as there are monocytes in the blood.

Because macrophages in the various tissues are all derived from the same bone marrow precursors and migrate to their sites of function as blood monocytes, it has been proposed that this widely distributed cellular system be viewed as a single functional unit and termed the *mononuclear-phagocyte system*<sup>758</sup> (see Chapter 8). In preference to the designation "reticuloendothelial (RE) system" the new term emphasizes the common origin and closely related functions of the macrophages. It also avoids the implication inherent in the

term "RE system" that reticular cells (fibroblasts and fibrocytes) and endothelial cells form part of the system. These cells are specifically excluded since they have different origins and are much less phagocytic than are macrophages<sup>758</sup>; the latter fact was appreciated by Aschoff (see Chapter 8, page 351).

Although the macrophages in various tissues have common ancestors and carry out similar functions they may assume different properties, behave somewhat differently kinetically, and undergo specialized transformations in various body sites, as indicated below.

### Peritoneal Macrophages

Macrophages can be readily harvested from the peritoneum for study and are considered typical "free" macrophages. Their origin from bone marrow via blood monocytes has been mentioned (page 267). Studies in mice showed the free peritoneal cell population to consist of  $5$  to  $7 \times 10^6$  cells, about one third of which were macrophages.<sup>92</sup> When lethally irradiated mice were given homologous bone marrow, thus enabling them to survive, the peritoneal macrophage population was gradually replaced by donor cells over a five- to six-week period<sup>92</sup>; turnover time as estimated from <sup>3</sup>HTdR studies gave similar values, namely 20 to 40 days.<sup>130</sup> The fate of the replaced cells is unknown. Less than 3% of peritoneal cells took up <sup>3</sup>HTdR *in vitro*; thus they divide rarely in normal animals.<sup>130,135</sup> However, after injection of foreign substances such as glycogen, differentiation of peritoneal mononuclear cells into macrophages was accelerated, both as observed morphologically and as judged from increased acid phosphatase activity; concomitantly there was an increase in DNA synthesis (<sup>3</sup>HTdR uptake).<sup>757</sup> In mice infected with *Listeria monocytogenes*, marked transformation occurred within 48 hours.<sup>761</sup> This consisted of an increase in <sup>3</sup>HTdR uptake from < 2% initially to 14% at 48 hours, an increase in phagocytic and bactericidal ability, and increased spreading on glass surfaces. Since the enhanced phagocytosis and

spreading (ie, transformation into avidly phagocytic macrophages) were blocked by iodoacetate it was presumed that these changes reflected fundamental metabolic alterations that are important for enhanced, cell-mediated host resistance. A similar but slower response to BCG infection occurred.<sup>761</sup>

### Alveolar Macrophages

Early studies suggested that there are two populations of alveolar macrophages, one with a turnover time of seven days and another with a turnover of 35 days.<sup>751,752,773</sup> Studies in mouse chimeras seemed compatible with this in that two thirds to four fifths of alveolar macrophages appeared to come from donor cells while the remainder were of host origin.<sup>765</sup> However, other workers, using different methods to harvest the macrophages, showed all alveolar macrophages to be of donor origin.<sup>133</sup>

### Liver Macrophages (Kupffer Cells)

In normal mice given <sup>3</sup>HTdR, less than 1.5% of Kupffer cells were labeled within the first two hours, thus indicating a low rate of cell division and turnover.<sup>762</sup> With time the labeling index increased, reaching a maximum about 24 hours after the peak of blood monocyte labeling. From these data the Kupffer cells also appear to come from blood monocytes. The turnover time of Kupffer cells was estimated to be 60 hours in normal mice.<sup>129,776</sup> However, just as with peritoneal macrophages, the presence of infection with *Listeria* or BCG elicited a marked increase of <sup>3</sup>HTdR uptake and local proliferation of macrophages, followed by changes in macrophage properties and function.<sup>762</sup>

### Splenic Macrophages

These cells also have been shown to come from precursors in the marrow<sup>133</sup> and to undergo little proliferation under normal conditions (less than 2% <sup>3</sup>HTdR uptake).<sup>761</sup>

After appropriate stimulation (see Chapter 8, pages 352-354) or in the presence of infection<sup>761</sup> an increase in spleen macrophage proliferation occurs and the macrophages become more phagocytic and more effective in killing organisms.<sup>761</sup>

### Osteoclasts

Osteoclasts have been shown to form from fusion of tissue histiocytes,<sup>755,756</sup> and in the regenerating salamander limb have a life span of less than 10 days.<sup>755</sup> Osteoclasts differ from most macrophages in that they do not take up trypan blue, but like most macrophages they possess a high concentration of acid phosphatase activity.<sup>755</sup>

### Fate and Possible Recirculation of Tissue Macrophages

The low turnover and large mass of tissue macrophages in several body sites have been described, but the ultimate fate of these cells is unknown. Thus, although some alveolar macrophages are lost in the sputum, others must remain in situ for long periods as evidenced by the persistence of carbon-containing macrophages in the lung and regional lymph nodes.

Another unresolved question is whether macrophages reenter the blood and move from tissue to tissue. Early studies using vital dyes and carbon particles were interpreted as indicating that Kupffer cells and splenic macrophages could enter the blood and become alveolar macrophages,<sup>760</sup> but more recent studies have not confirmed this.<sup>766,767</sup> The fate of intravenously injected peritoneal or alveolar macrophages and Kupffer cells has been studied; Kupffer cells preferentially return to the liver while alveolar or splenic macrophages were found mainly in the spleen.<sup>766,767</sup> The presence of histiocytes in the blood in bacterial endocarditis and other severe infections suggests that either macrophages may reenter the blood from the tissues or transformation of monocytes to macrophages occurs in the blood.<sup>754</sup>

### *Normal Values and Physiologic Variations*

The variations in blood monocyte concentration with growth and development are shown in Figure 2-11 and normal values for the adult are given in Table 6-4. To our knowledge, nothing is known concerning physiologic variations in blood monocyte levels in normal man.

### *Control Mechanisms Regulating Monocyte Production*

Monocytopoietic substances probably exist, but information on this subject is as yet very meager. A macrophage growth factor derived from fibroblast cultures has been described,<sup>783</sup> but what role it may play, if any, in monocyte pathophysiology remains to be elucidated. Also a "monocytogenic hormone" has been found in the serum of rats after injection of complete Freund's adjuvant into lymph nodes. This activity produces striking blood monocytosis and is thought to increase monocyte precursor proliferation.<sup>789</sup>

### *Properties and Functions of Monocytes and Macrophages<sup>770,841</sup>*

As with the neutrophil, the blood monocyte is thought to be en route to its major sites of action in the tissues; there it *transforms into the macrophage*, which is the more active cell form. After migration into rabbit ear chambers, monocytes were observed to increase in size, the cytoplasm became more clear, and colorless refractile droplets that stained with neutral red developed at the periphery. The cells were now called "resting histiocytes" and exhibited little movement or activity. They did not divide in uninfamed tissue, but they did ingest red cells in their immediate vicinity although showing little inclination to migrate toward distant cells.<sup>102</sup> Blood monocytes contain small numbers of peroxidase-positive granules, but these are not seen in peritoneal or alveolar macrophages harvested from normal mice or after culture<sup>778</sup>; thus the granules apparently are

lost or used up in the transformation from monocyte to macrophage, and the presence of peroxidase-positive macrophages is thought to reflect the recent influx of blood monocytes.<sup>778</sup> In vitro,<sup>806,820</sup> as compared to monocytes, macrophages exhibit more active pinocytosis and phagocytosis, increase in glycolysis, cellular respiration and number of mitochondria, and enhanced enzyme activity<sup>806,811</sup>; active synthesis of lysosomal enzymes also has been demonstrated in macrophages.<sup>820</sup> The enzyme load of macrophages varies considerably, depending on their source, stage of activation, and other factors. Among other observations<sup>817,841</sup> the amount and rate of enzyme synthesis and the type of enzymes synthesized appear to be related to the nature of the material ingested by the cell.<sup>806,811</sup> Macrophages in the alveoli appear to be chronically stimulated as compared to those derived from other sites.

In short, the monocyte-macrophage is not an end-stage cell and thus its properties and functions are more varied and complex than those of other phagocytes. The macrophage survives much longer in the tissues than do neutrophils, is capable of cell division and transformation, and can be stimulated to synthesize a variety of enzymes and other substances, depending on the needs of the moment.<sup>841</sup>

### *Endocytosis*

A study of the in vitro phagocytic abilities of human blood monocytes demonstrated their ability to ingest a variety of bacteria, fungi, sensitized red cells, and polystyrene particles.<sup>812</sup> Monocytes were more energetic than neutrophils in ingesting polystyrene particles, fungi, and sensitized erythrocytes, and less effective in ingesting the bacteria studied (staphylococci and *E. coli*). Serum was not necessary for the uptake of polystyrene particles, but serum or IgG greatly enhanced the ingestion of bacteria and fungi. Monocytes ingested sensitized erythrocytes and this action was inhibited by certain subgroups of IgG<sup>801</sup> but not by others or by IgM or albumin.<sup>800,812</sup> Erythrophagocytosis

progressed poorly in suspension cultures although rosettes were plentiful; thus monocytes appeared to require surface contact for ingestion of these large particles. Neutrophils did not form rosettes or ingest sensitized erythrocytes, and neither neutrophils nor monocytes ingested unsensitized, in vitro-aged red cells, or antibody or endotoxin-damaged neutrophils. Glycolysis is required for phagocytosis by monocytes, but the associated metabolic changes are less striking than for the neutrophil and have been less well studied.<sup>806,812</sup>

Macrophages appear to be heavily involved not only in the phagocytosis of bacteria and effete or damaged autologous cells, but also in the uptake of a variety of macromolecules (pinocytosis). In vitro, the rate of pinocytosis was shown to increase with the concentration of serum in the medium and with the content of certain molecules therein, either natural polysaccharides, nucleotides, proteins (including antibodies), or synthetic macromolecules.<sup>808</sup> The pinocytotic vesicles were observed to fuse with preexisting secondary lysosomes (phagosomes) and Golgi-derived primary lysosomes, thus establishing a link between endocytosis and the changes (lysosome formation and enzyme synthesis) that occur with differentiation. Although the processes of pinocytosis and phagocytosis are similar, their metabolic requirements appear to be different in that pinocytosis is inhibited by anaerobic conditions or by inhibitors of respiration and oxidative phosphorylation.<sup>806,815</sup>

### Chemotaxis<sup>851</sup>

As with the neutrophil, monocytes or macrophages may come in contact with bacteria, effete cells, or other particles either by chance, as a result of chemotactic factors, or by virtue of antibody activity. It has been demonstrated that certain direct-acting chemotactic factors (cytotoxins from bacterial cultures) have greater attraction for neutrophils than for macrophages, while normal serum (not plasma) is more chemotactic for macrophages. Separation of normal serum on

Sephadex columns revealed that the macrophage chemotactic activity resided in a high molecular weight fraction (160,000 to 250,000 MW) while several fractions of lower molecular weight (5,000 to 35,000) were most attractive to neutrophils.<sup>851</sup> Plasma is not chemotactic for either cell type, but it has been shown that plasmin splits complement into neutrophil-active agents (C3<sub>a</sub> and C5<sub>a</sub>), and plasmin interaction with serum generates macrophage chemotactic activity. Thus the coagulation system appears important in the chemotactic attraction of monocytes and macrophages. There also is in vitro evidence that sensitized lymphocytes react with antigen and release factors chemotactic for macrophages.<sup>851</sup> As yet, macrophage chemotactic factors are less well understood than are factors attractive to neutrophils.

### Particle Recognition<sup>452,851</sup>

It has long been known that the ingestion of most particles by phagocytes is enhanced by factors in serum, specific antibody, complement, natural antibody, or perhaps still other factors. IgG antibodies facilitate attachment and uptake of erythrocytes by monocytes and macrophages.<sup>832</sup> There appear to be at least two different types of receptor sites for immunoglobulins on macrophages. The receptor site for 7S immunoglobulin does not require Ca<sup>++</sup> while 19S binding required Ca<sup>++</sup>. Both receptor sites are resistant to treatment with trypsin and thus are distinct from complement receptors.<sup>833</sup> Neutrophils and monocytes appear to have receptors for 7S but not for 19S immunoglobulin. Macrophages are able to bind certain antibodies (cytophilic antibody) and thus facilitate particle contact, but the role of this process in particle recognition is not yet understood. Some particles are ingested in the absence of serum recognition factors (eg, polystyrene, silica, glass) presumably because their surfaces are naturally attractive to phagocytes. Other particles resist attachment and appear to possess antiphagocytic properties, eg, the polysaccharide capsule of pneu-

mococci, the M protein and hyaluronic acid of streptococci, and the polyglutamic acid capsule of the anthrax bacillus. Bacteria or erythrocytes can be artificially opsonized by treating them with certain metals, tannic acid, or by other means that probably alter the particle surface. The activation of complement probably also results in alterations of particle surfaces and thus enhances adsorption and phagocytosis. A comparison of phagocytosis by insect hemocytes, "facultative" phagocytes such as tissue culture fibroblasts, and "professional" phagocytes (neutrophils, monocytes, and macrophages) has led to the suggestion that professional phagocytes differ from other cells in possessing receptor sites for immunoglobulins. It is proposed that this property serves to greatly enhance their ability to recognize and ingest foreign particles.<sup>845</sup> In the absence of such receptor sites the binding and uptake of particles by other tissue cells appear to depend on some crude means of recognition that identifies some basic property of the particle surface that is required for adsorption (perhaps affinity for aqueous or fatty substances or appropriate charge).

### Ingestion<sup>839</sup>

The mechanism by which a cell is triggered to ingest particles adsorbed to its surface is not known. It has been hypothesized that the cell recognizes a conformational change which occurs when antibody reacts with antigen,<sup>843</sup> but this does not explain the ingestion of inert particles (glass, polystyrene) in the absence of serum.<sup>839</sup> Studies of ingestion using polystyrene spheres of increasing size led to the suggestion that phagocytosis is triggered when a large enough surface area of the phagocyte reacts with the particle; however, this does not explain how a macrophage can adsorb to its surface several aldehyde-treated erythrocytes in balanced salt solution but will not ingest them unless opsonins also are available.<sup>839</sup> Perhaps aldehyde treatment alters the erythrocyte membrane enough to facilitate adsorption, but something more is needed to activate ingestion.

As with the neutrophil and monocyte, phagocytosis by macrophages requires *energy expenditure*. This is derived from anaerobic glycolysis.<sup>806,819</sup> An important exception is the alveolar macrophage which relies heavily on aerobic metabolism for its metabolic needs<sup>784,806</sup> and requires an oxygen tension greater than 25 mm Hg for maximal phagocytic activity.<sup>815</sup> Pinocytosis requires oxidative phosphorylation and is suppressed by inhibitors of respiration; thus it appears to be a somewhat different process than that of phagocytosis.<sup>819,845</sup> New protein formation also is required for continuing pinocytosis and the process is inhibited by puromycin or cycloheximide; presumably this reflects a requirement for new plasma-membrane formation.<sup>819</sup> Phagocytosis by the macrophage is accompanied by an increase in glycolysis, oxygen uptake, conversion of the 6 carbon of glucose to CO<sub>2</sub>, and other changes that also accompany phagocytosis by neutrophils and monocytes (see page 259). However, the increases are much less striking than those for neutrophils and are similar to those of the monocyte.<sup>784,806</sup> The relationship of these metabolic events to particle uptake, bacterial killing, and associated processes is even less clear than for the neutrophil.

The bactericidal properties of monocytes and macrophages are well documented since, within 20 minutes, susceptible ingested organisms are killed. However, very little is understood about how this is accomplished.<sup>806,811</sup> In contrast to neutrophils, monocytes and macrophages lack phagocytin, and cationic proteins and macrophages lack peroxidase. Both possess lysozyme and thus can split the B-1,4 glycosidic bond between N-acetylglucosamine and N-acetylmuramic acid in bacterial cell walls, but few organisms are sensitive to lysozyme in their native state. Some but not all monocytes deficient in myeloperoxidase have been shown to be deficient in fungicidal properties<sup>508</sup>; thus this enzyme must play some part in microbicidal action, but alternative mechanisms for bacterial killing appear to exist in its absence.<sup>504</sup> Once ingested, pinosomes or phagosomes move toward the nucleus and fuse with pri-

primary lysosomes or preexisting secondary lysosomes, thus being converted to secondary lysosomes (Fig. 6-10A). Colchicine may interfere with the movement of organelles that precedes fusion.<sup>837</sup> A significant difference from neutrophils is that monocytes and macrophages can synthesize new enzymes and replace expended lysosomes,<sup>818</sup> thus giving them more staying power in combating infection and inflammation.

Digestion of endocytized material proceeds in the acid environment of the secondary lysosome under the influence of the spectrum of enzymes present. Metabolic blockers do not inhibit digestion,<sup>490</sup> and only a marked reduction in ambient temperature will interfere.<sup>819</sup> Once started, digestion is rapid, over 80% of isotope from iodinated albumin, gammaglobulin, or hemoglobin being released from the cell into the medium in 20 hours. Labeled bacteria also are digested rapidly, but those coated with immune sera are degraded less rapidly than are uncoated organisms.<sup>490</sup> Digestion of sugars to molecules smaller than 200 molecular weight is accomplished before release from the lysosome; peptides are degraded at least to tripeptides before release.<sup>819</sup> Some materials are digested with difficulty or not at all and accumulate within the secondary lysosome<sup>819</sup>; in vitro examples are sucrose, ficoll, dextran sulfate, inulin, D-amino acid and di- and tripeptides.<sup>819</sup> In man the accumulation of indigestible materials in macrophages may lead to disease, as in the case of the lipoidoses (see Chapter 42), silicosis, and other granulomatous processes.

The synthesis and secretion of a variety of biologically active substances by cells of the monocyte-macrophage system are now fairly well established and include components of the complement system, transferrin, interferon, endogenous pyrogen, lysozyme, and colony stimulating factor.

Incorporation of <sup>14</sup>C-labeled amino acids into the third component of complement (C3 or  $\beta_{1c}$ ) and transferrin was accomplished by rat peritoneal exudate cells but not by thoracic duct lymphocytes.<sup>853</sup> In other species (mouse, rabbit, guinea pig, monkey, and

man), peritoneal and alveolar macrophages also produced B<sub>1</sub>C, but only mouse and rat cells produced transferrin. Human and monkey macrophages produced the C4 and C1<sub>q</sub> components of complement, perhaps C5 and C6 and also IgG. It should be noted that the synthesis of complement is accomplished by a variety of other cell lines as well, including tissue-culture fibroblasts, probably hepatocytes, and the guinea pig columnar epithelial cells of the intestine.<sup>853</sup>

Interferon production is a property of blood monocytes and peritoneal or alveolar macrophages. Polymorphonuclear neutrophils, spleen cells, and kidney cultures also produce interferon after viral infection, but macrophages produce larger amounts.<sup>853</sup> Exposure of cells to actinomycin inhibits interferon production. In vivo, in mice a major source of interferon production is the spleen as judged from drastic reduction in circulating levels after splenectomy.<sup>803</sup>

Endogenous pyrogen is produced by human blood monocytes and alveolar macrophages after phagocytosis of bacteria<sup>807</sup> and exposure to other stimuli<sup>545</sup>; new protein synthesis is required and the process is time and temperature dependent.<sup>540</sup>

Lysozyme has been identified histochemically in monocytes as well as neutrophils.<sup>809</sup> Increased levels were observed in the liver, spleen, blood, and kidneys during the period of increased resistance to infection induced by the administration of BCG to mice,<sup>827</sup> and very high levels have been measured in the serum and urine of patients with myelomonocytic leukemia.<sup>550</sup>

Macrophages and blood monocytes of man also have been shown to be a source of colony-stimulating factor<sup>546a</sup>; presumably this material is synthesized by them and secreted.<sup>828</sup>

### Other Secretory Reactions of Monocytes

The monocyte also appears to be essential for the mixed leukocyte culture reaction<sup>829</sup> and lymphocyte transformation.<sup>813</sup> Small numbers of viable, sensitized monocytes (1

per 100 lymphocytes) after exposure to antigen produce an RNA species that is transmitted to lymphocytes by direct cell contact, thus mediating lymphocyte transformation. The process is demonstrable only when lymphocytes and monocytes from the same individual are used.<sup>813</sup>

After the ingestion of silica particles, macrophages release a substance that stimulates collagen formation by fibroblasts.<sup>831</sup> Although not yet characterized, this factor is produced in macrophages damaged by the ingestion of certain toxic particles; it is not present in normal macrophages.<sup>803</sup>

In addition to the above, it is clear that macrophages contribute to the antibody response by trapping antigen in lymph nodes and other sites, presumably by pinocytosis, phagocytosis, and/or retention of antigen on membrane surfaces. By some means the antigen may be processed into more antigenic forms and these apparently can be stored for long periods or transmitted to immunocompetent cells to stimulate antibody production. The details of these processes are as yet poorly understood. They have been reviewed in several articles and books.<sup>808,823,825,841,848,856</sup>

The role of monocytes and macrophages in cellular immunity also is of great importance to body defenses.<sup>835</sup> It is now known that the injection of antigen into previously sensitized animals activates sensitive cells (lymphocytes) to release a variety of substances that recruit nonsensitive monocytes and macrophages to the area.<sup>821,858</sup> A common example of this process of delayed hypersensitivity is provided by the tuberculin skin test.

Fig 7-1 A, Lymphocyte obtained from normal peripheral blood. Arrow indicates centriole. The cytoplasm shows mostly single ribosomes and few profiles of rough endoplasmic reticulum (ER). G = Golgi zone (Magnification X13 500). B Plasma cell shows cytoplasm filled with rough endoplasmic reticulum and polyribosomes shown at higher magnification in D (Magnification X6000). C, Detail of the cytoplasm of a resting lymphocyte, possessing mostly single ribosomes should be compared with D which shows the cytoplasm of a stimulated lymphocyte (Magnification X46,000). D, Detail of the cytoplasm of a stimulated lymphocyte or lymphocytoid plasma cell shows polyribosomes and profiles of rough ER. This is also typical for a cell that has responded to antigen or any mitogenic agent (Magnification X46,000) (Courtesy of Dr Dorothea Zucker-Franklin).

have been seen *in vivo* under conditions of antigenic stimulation.<sup>1,13</sup> Transformation is accompanied by a number of well-defined biochemical changes (page 341). Morphologically, such cells more closely resemble large lymphocytes. They range in diameter from 10 to 20  $\mu\text{m}$  and may display bizarre shapes. The nucleus is relatively large and leptochromatic, and contains one or more large nucleoli. The cytoplasm usually is abundant and intensely basophilic. The EM appearance of stimulated lymphocytes, and particularly that of their nuclear components, depends on the mitotic phase of the cell cycle.<sup>21,31</sup> The endoplasmic reticulum is not strikingly developed in PHA-stimulated cells, but it is in those triggered by other agents such as pokeweed mitogen (PWM).<sup>9</sup> The cytoplasm also contains numerous ribosomes and polyribosomes, an expanded Golgi apparatus, and an increased number of mitochondria as well as lysosomes, lipid inclusions, and vacuoles. Mitotic forms are frequent.

### Plasma Cells

Plasma cells probably are progeny of lymphocytes<sup>8</sup> although some contend that they constitute a separate and independent cell line.<sup>17</sup> Morphologically, they are easily differentiated from other cell types (Plate VII). The cells are spherical or ellipsoidal and range from 5 to 30  $\mu\text{m}$  in size. The cytoplasm is abundant and is always basophilic, usually deep blue; it may have a granular character. Plasma cells have a well-defined perinuclear clear zone which contains the Golgi apparatus. In supravital prepared films, the cytoplasm of plasma cells is deep yellowish gray. The nucleus is small in relation to the cell size; it is round or oval, eccentrically placed, and contains dense masses of chromatin, often arranged in a wheel-spoke fashion ("Radkern").

With the *electron microscope* (Fig. 7-1B) the surface membrane and the nucleus appear similar to those of the lymphocyte. The cytoplasm of the plasma cell is characterized by a well-developed rough endoplasmic reticu-

lum which fills most of the cytoplasmic space, except in the area of the perinuclear clear zone which contains the Golgi apparatus. The endoplasmic reticulum consists of parallel lamellae arranged in various patterns, usually in parallel convolutions. The inner surfaces of the lamellae are quite smooth and form the walls of spaces (cisternae) filled with amorphous products of varying density. The outer aspects of the lamellae are rough because of attached ribosomes. A few mitochondria may be seen.

### Intermediate Forms

The above-described EM appearance of lymphocytes and plasma cells is the one most typical of the respective cells. Often, however, *intermediate forms* are found.<sup>31</sup> Thus some cells may resemble small lymphocytes morphologically, but may contain an unusually well-developed rough endoplasmic reticulum. Such "intermediate cells," sometimes referred to as *lymphocytoid plasma cells* or *plasmacytoid lymphocytes*, are common in the blood of patients with plasma cell dyscrasias,<sup>30</sup> and of those with immunologic diseases characterized by hypergammaglobulinemia.<sup>29,30</sup> Similar cells have been encountered in the blood of patients suffering from viral infections ("*Türk cells*");<sup>3</sup> including infectious mononucleosis, as well as in the blood of apparently healthy individuals.<sup>31</sup> Alternatively, immature plasma cells may have an appearance more akin to that of PHA-transformed cells (Fig. 7-2); the nucleus is large and leptochromatic and the cytoplasm contains a rather simple endoplasmic reticulum, but many ribosomes and polyribosomes are present. Thus it is often difficult to draw sharp cytologic dividing lines.

## Histology of Lymphatic Tissues<sup>15</sup>

### Thymus

The thymus is a pinkish gray, lobed mass of tissue lying in the anterior, superior mediastinum. In relation to total body weight, it attains its greatest size during fetal develop-

Fig 7-2 Phytohemagglutinin-stimulated lymphocytes showing characteristic 'blast' cell transformation. The nucleoli are particularly prominent. The cytoplasm develops polysomes, rough ER, and some inclusions of unknown identity (Magnification X3600) (Courtesy of Dr. Dorothea Zucker-Franklin)

ment and the first two years of life. At birth it weighs about 10 to 15 g and it continues to grow (though relatively more slowly than the rest of the body), reaching a maximum of 30 to 40 g at puberty. From then onward it

involutesc slowly but remains substantial, even in old age (10 to 15 g), and continues to be very active in lymphopoiesis (see page 301).

The thymic lobes are surrounded by a capsule of connective tissue that sends septa

# PLATE VII

Fig 7-4 Lymph node *A*, Diagram showing the framework of the node as it would appear if the lymphocytes were removed from it *B*, Cross section of a normal lymph node showing lymphatic follicles (LF), germinal centers (GC) medullary cords (MC), and paracortical (PC) lymphoid areas (*A*, from Ham,<sup>15</sup> courtesy of the author and J. B Lippincott Company *B* courtesy of Dr J Hoogstraten, Department of Pediatrics, University of Manitoba)

On section each node can be seen to contain a readily distinguishable cortex and medulla (Fig. 7-4A). The entire structure is surrounded by a connective tissue capsule which sends septa or trabeculae into the substance of the node. The trabeculae provide support and carry blood vessels. The spaces between the trabeculae contain a mesh of *reticular fibers* (Fig. 7-4A). These areas of fine mesh are the sites of "primary follicles" in the cortex and of "medullary cords" in the medulla (Fig. 7-4B). Afferent lymphatic vessels penetrate the capsule to drain lymph into the subcapsular sinus, the latter being a zone of coarse mesh interposed between the capsule and the lymphatic tissue through which fluid percolates easily. The afferent lymphatic vessels start in the tissues as capillaries with blind endings and transport lymph fluid to regional lymph nodes where it is filtered before leaving via the efferent lymphatics. The efferent lymphatics exit on the hilar side to empty into the thoracic or the right lymphatic ducts, which in turn drain into the venous circulation. The centripetal flow of lymph is assured by one-way valves, in both afferent and efferent vessels.

Arteries enter and veins leave lymph nodes at the hilus. The circulation of blood through lymph nodes will be discussed in a subsequent section (page 303).

The cortex contains globular masses of lymphocytes known as *follicles*. In post-natal life (see below) follicles develop a paler looking central area known as a "*germinal center*." Here the cells are larger and have more cytoplasm, and the nuclei therefore appear to be fewer and farther apart. Many mitotic figures may be seen.

In contrast to the cortex, the medulla contains collections of lymphocytes arranged in the shape of cords. They are thought to be extensions of primary follicles into the medulla, and usually contain a large number of plasma cells, which may account for as much as half the cell population of the medullary cords.

The parafollicular areas of lymph nodes also contain small lymphocytes, but they are not arranged in any particular pattern and appear to subserve a different immunologic

function than their follicular fellows (see below).

### Nonencapsulated Lymphatic Nodules

Nonencapsulated lymphatic nodules are dense collections of lymphocytes commonly found in loose connective tissue, most frequently in close proximity to the lining epithelium of the upper respiratory tract, the alimentary tract, and the urinary tract. In some areas, such as the tonsils, the contact between epithelium and lymphoid tissue is most intimate. Because lymphatic nodules are not encapsulated, their periphery is often poorly defined. When they lie in close proximity to each other, as in the Peyer's patches of the lower small bowel, they may appear to be confluent. Nonencapsulated lymphatic nodules may sometimes acquire germinal centers.

### Spleen

A discussion of splenic structure, circulation, and function is found in Chapter 8.

### Bone Marrow

The anatomy of the *bone marrow* is discussed in Chapter 2.

## Development of the Immune System

Current concepts regarding the development and differentiation of the lymphoid system (Fig. 7-5) are derived from critical observations of certain developmental abnormalities of man, and from ontogenic, phylogenetic, and experimental studies of animal systems.

One of the earliest insights into the development of the immune system was provided by the clinical studies of immune deficiency states in man. It was found, for instance, that some individuals developed small lymphocytes normally but lacked plasma cells and antibodies, whereas others had defects of small lymphocytes and cellular immunity but re-

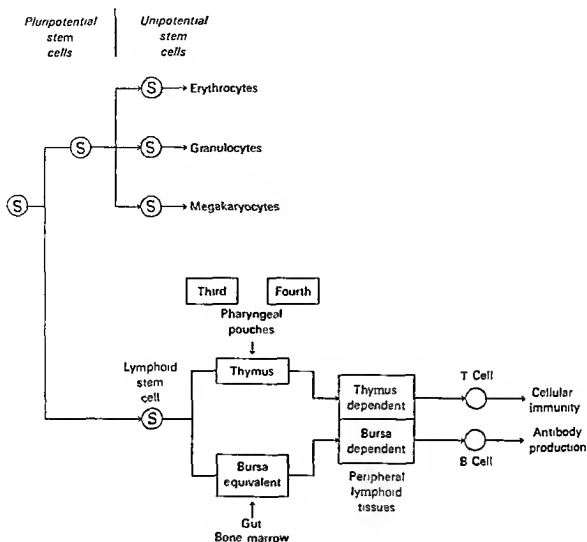

Fig 7-5 The development of the lymphoid system S = stem cell See text for details

tained a normal plasma cell and immunoglobulin system. The first type of defect is best exemplified by Bruton's agammaglobulinemia (see Chapter 44),<sup>36</sup> whereas the selective cellular defect was first discovered in patients with Hodgkin's disease<sup>43</sup> and, later, in patients suffering from the DiGeorge syndrome (Chapter 44). These observations provided the first suggestion of a dichotomy within the immune system, one branch subserving the production of circulating antibodies, the other, cell-mediated immune responses. Still other patients were found to have combined defects, such as those suffering from severe combined immune deficiency

(Chapter 44), and the defects were eventually attributed to absent or malfunctioning stem cells that normally feed both branches of the immune response.

Additional insights came from recognition of the fact that the cellular or humoral immune responses of experimental animals could be ablated selectively.<sup>40,41</sup> Thus it was found that the *bursa of Fabricius*, a hindgut lymphoid organ lying adjacent to the cloaca of birds, was essential for the development of humoral immunity<sup>43</sup> and that its removal, especially when followed by nearly lethal irradiation in newly hatched chicks, led to an absence of plasma cells, immunoglobulins,

and germinal centers in the spleen.<sup>38,40</sup> In addition, these birds could not be induced to produce antibodies, although they maintained normal levels of circulating lymphocytes and rejected foreign skin grafts with vigor. Bursectomized-irradiated chickens subsequently injected with bursal lymphocytes developed fairly normal numbers of plasma cells and germinal centers and produced immunoglobulins, although antibody production remained impaired.<sup>39</sup> Partial restoration could also be achieved by implanting bursal tissue within millipore chambers, suggesting that the bursa may also elaborate a humoral substance that acts on peripheral lymphoid cells.<sup>43</sup>

On the other hand, newly hatched birds irradiated and *thymectomized*, instead of being bursectomized, were found to have low circulating lymphocyte counts and their splenic white pulp was found to be depleted of small lymphocytes. Functionally, cellular immune responses such as delayed hypersensitivity reactions, homograft rejection, and graft-versus-host disease (see page 325 for definitions of these terms) were impaired.<sup>40</sup> These animals did, however, develop plasma cells and germinal centers and produced antibodies, albeit at significantly reduced titers.<sup>38</sup> Similar findings were noted in neonatally thymectomized rodents such as mice, rats, hamsters, and rabbits<sup>47</sup>; generally speaking, cell-mediated immune responses were greatly impaired, but only some circulating antibody responses were similarly affected. The latter usually involve thymus dependent antigens such as sheep red cells and bovine serum albumin,<sup>47</sup> ie, antigens that require the co-operation of thymus dependent and bursa dependent cells in antibody production (see page 316). Neonatally thymectomized animals give near-normal responses to thymus independent antigens such as pneumococcal polysaccharides and *Salmonella* flagellar antigen.<sup>47</sup> At least partial restoration of thymic function can be achieved by implanting thymic tissue in cell-tight millipore chambers, thus suggesting a thymic humoral mediator.<sup>46,48,49a</sup>

Although mammals do not have a bursa,

there is good evidence that, in the rabbit at least, gut-associated lymphoid tissue found in Peyer's patches, the appendix, and the sacculus rotundus may serve as bursal equivalents.<sup>41</sup> Others have suggested that the bursal equivalent of mammals may be dispersed throughout the body or that the bone marrow itself may be such a site.<sup>35</sup>

On the basis of these and other observations,<sup>41,45</sup> Good and his coworkers constructed the following scheme of lymphoid development (Fig. 7-5): Multipotential, undifferentiated stem cells from such sources as the area vasculosa of the yolk sac, the fetal bone marrow, or the fetal liver are thought to be capable of developing along several distinct lines depending on the specialized epithelia with which they come in contact. The epithelial components of the thymus and the bursa (or bursal equivalents) are thought to provide a microenvironment suitable for such differentiation. To emphasize the critical developmental role of these gut-associated tissues, the thymus and bursa, as well as the bone marrow, are referred to as "*central*" or "*primary*" lymphoid organs. Lymphoid stem cells coming into contact with thymic epithelium would be induced to differentiate into small lymphocytes capable of mediating cellular responses, whereas lymphoid precursor cells coming under the influence of the bursa or its mammalian equivalent would eventually differentiate into antibody-producing plasma cells.

The central lymphoid tissues serve to populate and maintain well-defined representative areas in "*peripheral*" or "*secondary*" lymphoid tissues such as the lymph nodes and the spleen; the thymus is considered to populate and maintain the paracortical areas of lymph nodes and the white pulp of the spleen, which are known to subserve cellular immune function, including delayed hypersensitivity reactions, homograft rejection, graft-versus-host disease, and helper functions in certain types of antibody responses (page 316). The bursa or its equivalent is thought to be responsible for populating and maintaining the lymphatic follicles of lymph nodes and spleen, as well as the medullary cords of

†In birds

lymph nodes, all of which are concerned with antibody production. In addition to supplying precursor cells, the central lymphoid organs may also provide humoral substances that promote maturation of immunocompetent cells. The crucial link between the central and peripheral areas on the one hand and their respective functions on the other is provided by extirpation experiments, the study of human immune deficiency states, and the immunization of animals by techniques that stimulate either antibody production or cellular immunity, with ensuing characteristic morphologic changes in the appropriate thymus or bursa (equivalent) dependent areas.

### T and B Cells

Differentiated lymphocytes subserving antibody production are now referred to as *B cells* (bursa dependent or bone marrow dependent cells) whereas those involved in

cellular immune functions (see below) are referred to as *T cells* (thymus dependent cells). The structural and functional properties of these cells are summarized in Table 7-1 and will be discussed in subsequent sections of this chapter.

In the laboratory T cells and B cells are most readily identified by the presence or lack of distinguishing *surface markers*.<sup>33a,35b,42,43a</sup> Thus *B cells* are characterized by the presence of membrane-bound immunoglobulin (Ig), which may be identified by immunofluorescence or other techniques.<sup>35b,42</sup> In the peripheral blood, 10 to 20% of lymphocytes have membrane-bound Ig.<sup>42</sup> IgM (see page 311) appears to be the predominant immunoglobulin class (one half to two thirds) and IgG accounts for most of the remainder. IgA, IgD, and IgE are rarely found.<sup>42</sup> Approximately 25 to 50% of lymphocytes found in lymph nodes, tonsils, and the spleen also bear Ig on their surface.<sup>42</sup> In addition, *B cells* are

Fig 7-6. Scanning electron micrograph of T cells (*top*) and B cells (*bottom*) (From Pollack et al,<sup>42a</sup> courtesy of the authors and the Journal of Experimental Medicine)

characterized by the presence of receptors for complement (C3) (page 334), but only one half of the peripheral blood cells bearing Ig markers can be so identified.<sup>35b</sup> Another useful distinguishing characteristic is the presence of a receptor for the Fc portion (see page 306) of Ig. This receptor is best demonstrated by the uptake of aggregated gamma globulin on the cell surface.<sup>35b,42</sup>

T cells lack readily identifiable surface immunoglobulin, Fc receptors, or complement receptors. They are most readily identified by their ability to form rosettes with sheep red blood cells, presumably because of the presence of a specific (non-antibody) receptor for such cells.<sup>35a,35b,42</sup> Approximately 69 to 82% of peripheral blood lymphocytes form such rosettes.<sup>35b</sup> B cells do not form sheep red cell rosettes.<sup>35a</sup> Unfortunately a specific T cell marker, such as the  $\theta$  (theta) antigen of mice,<sup>43b</sup> has not yet been identified in man, although several laboratories have succeeded in producing anti-T cell sera of considerable specificity.<sup>35b</sup>

B and T lymphocytes may also be distinguished on the basis of their appearance under the scanning electron microscope (Figure 7-6). T cells show a generally smooth surface, whereas B cells are coated with microvilli.<sup>48a</sup>

## Lymphokines

### Stem Cells

Since a significant number of lymphocytes die or are lost each day, while the total number of cells remains relatively constant, an efficient way of replacing cell loss must exist. The source of cell replacement is the stem cell compartment, the general characteristics of which are described in Chapter 2.

Inferential evidence suggests that hematopoietic stem cell compartments exist at various levels of differentiation (Chapter 2). Thus it appears that lymphocytes ultimately descend from primitive pluripotential stem cells arising in the area vasculosa of the yolk sac.<sup>99</sup> Such cells seem capable of differentiating further into stem cells with more restricted capabilities, such as those that feed into the lymphoid system and those that give rise to

other hematopoietic cells<sup>91</sup> (Fig. 7-5). Finally, lymphocytes themselves appear to form a highly differentiated stem cell compartment since they are capable of blastic transformation, cell division, and eventually reversion to small lymphocytes (page 341).

It is probable that under normal circumstances, the most mature unipotential stem cells feed the lymphoid, erythrocytic, and other compartments. If one of these mature stem cell compartments is damaged, or if there is an excessive demand for cells, more and more primitive progenitors are called upon to feed into the more differentiated compartments.

In the adult, pluripotential hematopoietic stem cells capable of lymphoid and non-lymphoid development, as well as more highly differentiated stem cells, occur in the marrow,<sup>75,91,115</sup> and to a lesser extent in the blood.<sup>54,91</sup> They are also found in the fetal bone marrow and liver<sup>78</sup> but not in other lymphoid tissues.<sup>91</sup>

### Lymphocytes

#### Total Mass

The lymphoid tissues in the aggregate constitute a major organ system,<sup>20</sup> but precise measurements of the total number of lymphocytes in the body of man have not been performed because of the distribution of lymphocytes among a large number of anatomical compartments and their dispersion in organs such as the liver, lungs, and skin.

In rats, attempts have been made to quantitate the total lymphoid mass by combined measurements of organ volumes and estimates of lymphocyte numbers in tissue sections.<sup>83</sup> Others have combined differential counting of tissues containing lymphoid and nonlymphoid cell lines with determinations of the total organ DNA content. The latter, because of its fixed value in diploid cells, provides an accurate estimate of total cell number.<sup>86</sup> With the latter technique it has been estimated that the lymph nodes, thymus, and spleen of rats weighing 200 g contain about  $4 \times 10^9$  lymphoid cells,<sup>86</sup> and that the total lymphoid mass of young rats is of the order

of 0.5 to 1.0% of body weight.<sup>51</sup> These figures probably represent underestimates.<sup>123</sup>

In the calf, estimates of total cell numbers based on prolonged thoracic duct drainage indicate that the total population of lymphocytes exceeds  $10^{12}$  cells.<sup>20</sup> Cannulation of the human thoracic duct yields up to  $3.5 \times 10^{11}$  lymphocytes during the first 60 days of drainage, and about  $0.8 \times 10^9$  daily thereafter.<sup>109</sup> Since these lymphocytes represent only one of the major lymphatic compartments (page 303), it is likely that the total lymphocyte population of adult man also exceeds  $10^{12}$  cells, or about 1 kg of tissue.

### *Techniques for Studying Lymphocyte Kinetics*

**MITOTIC NUMBERS.** Kindred<sup>98</sup> studied the mitotic index of lymphoid tissues. Others have used the rate of metaphase accumulation after mitotic arrest to estimate mitotic activity.<sup>67,87</sup> Knowing the mitotic index ( $m$ ) (expressed as percent of cells in mitosis), the size of the precursor pool ( $N$ ), and the mitotic time in hours ( $t$ ), it is possible to calculate lymphocyte production ( $P$ ) for any organ according to the formula  $P = N \frac{m}{t}$ . The mitotic index may also be used to estimate the "turnover time" of cell populations, i.e., the time it would take to renew all cells within a population, assuming, of course, that all cells within a given compartment have the same proliferative potential. Thus, if the mitotic index of the superficial thymic cortex of rats four hours after administration of colchicine is 4.106%, the turnover time for the entire compartment would be 4.05 days.<sup>87</sup> Values calculated in the same species for other compartments include the following: deep thymic cortex 5.50 days, thymic medulla 13.08 days, lymph node germinal centers 2.40 days, spleen germinal centers 1.79 days, and medullary cord 8.66 days. Turnover times for the outer zone of lymphoid follicles and the paracortical areas could not be calculated because of negligible mitotic activity in these areas. The mitotic indices of peripheral blood and thoracic duct lymphocytes are also low<sup>61</sup>; thus few of these cells are dividing.

**ISOTOPIC DNA LABELING.** Isotopic DNA labeling techniques depend on the incorporation of labeled precursors into the DNA of DNA synthesizing cells. Early studies employed radioactively labeled phosphates ( $^{32}\text{PO}_4$ ),<sup>123</sup> but more recent studies have utilized isotopically labeled thymidine ( $^3\text{H}$  or  $^{14}\text{C}$ ) predominantly.<sup>68,507</sup> This precursor is particularly useful, since its incorporation into DNA may be assessed by radioautographic techniques as well as by the determination of DNA specific activity. It has been used in several different types of studies: (1) If labeled thymidine is given as a single intravenous injection, its relatively rapid clearance from the circulation results in the flash labeling of a cohort of cells synthesizing DNA at that particular time. (2) If the precursor is continuously infused over a period of days or weeks, it will be incorporated into a progressively larger population of cells, as more and more of them pass through the DNA synthetic phase. The rate of increase and the time required to label all cells reflect the rate of renewal in the system. This use of  $^3\text{HTdR}$  is illustrated in Figure 7-7 which shows the rate of appearance of labeled lymphocytes in various tissues during a prolonged period of  $^3\text{HTdR}$  infusion<sup>68</sup>: The small lymphocytes of bone marrow showed the fastest rate of turnover; essentially 100% of these cells were labeled after 4 days, and their half-time renewal rate was 24 hours. The thymus was second with a half-time renewal of 36 hours, followed by spleen, mesenteric lymph nodes, and, finally, thoracic duct lymph. The blood is the only tissue that shows a sharp break in the slope of the labeling curve at four to five days. The two parts of the curve were thought to reflect two populations of cells, each with different life spans (below). (3) Once a cell has been labeled, the dilution of the label by newly synthesized DNA can be used as an index of cell division. The dilution of the label may be determined by radioautography for single cells, or by determining DNA specific activity for populations of cells. However, reutilization of the label complicates interpretation.<sup>109</sup> (4) Isotopically labeled cells may be used to trace their migration patterns. Cells may be labeled

Fig 7-7 The rate of appearance of labeled lymphocytes in various lymphoid compartments in rats during the continuous infusion of tritiated thymidine ( $^3\text{HTdR}$ ). MLN refers to mesenteric lymph nodes, TDL, to thoracic duct lymphocytes (From Everett and Tyler<sup>48</sup> courtesy of the authors and International Review of Cytology)

in vitro and re injected, or specific compartments such as thymus or bone marrow may be labeled by careful local injection of precursors. (5) Precursors such as  $^3\text{HTdR}$  are also useful for the assessment of lymphocyte proliferation under in vitro conditions (page 341).

All these techniques have been used to define the kinetics of lymphopoiesis in various lymphocyte compartments such as the bone marrow, the thymus, the lymph nodes, and the peripheral circulation.

### The Life Span of Lymphocytes

When applied to cells capable of self replication (such as lymphocytes), the term "life

span" usually refers to the intermitotic interval. Sometimes the term is applied to the time between cell division and death, of necessity related events, since mitosis must be followed by the eventual elimination of one of the resulting pair if the total number of cells is to remain constant.

Based on the mistaken belief that thoracic duct lymphocytes are newly formed and on the discovery that the number entering the blood daily from that source is sufficient to replace the peripheral blood lymphocytes several times each day, it was believed for many years that the life span of lymphocytes did not exceed three to four days.<sup>20</sup> In 1954 Ottesen<sup>101</sup> deduced the existence of two populations of cells from experiments in which

he administered  $^{32}\text{P}$  to human subjects and observed the subsequent decay of radioactivity in DNA isolated from peripheral blood lymphocytes: 20% had a mean life span of two to three days, and the remainder a mean life span of 200 to 300 days. Others showed that few lymphocytes from the blood or thoracic duct became labeled after single injections of labeled thymidine, in both *man* and laboratory animals, again suggesting that these cells have a long life span (intermitotic interval).<sup>11</sup>

The studies of Ottesen and others were criticized on the grounds that the long persistence of label in some cells might simply indicate reutilization of the label by succeeding generations of cells.<sup>11</sup> These criticisms did not apply to studies in which label was infused continuously and the number of unlabeled cells was determined. In one such study it was found that after 220 days of continuous infusion of  $^3\text{HTdR}$  into rats, 10% of circulating lymphocytes were still unlabeled and that in one animal 5% remained unlabeled after 270 days.<sup>106</sup> From estimates of the rate at which labeled cells accumulated after repeated injections, it was calculated that in the rat, 90% of the small lymphocytes of the thoracic duct were long-lived, whereas the corresponding figures for blood, mesenteric lymph nodes, and spleen were 66%, 75%, and 25%, respectively. Almost all the small lymphocytes in the thymus and bone marrow were short-lived.

In man the majority of circulating lymphocytes are long-lived. The average life span (intermitotic period) of these cells has been estimated at 4.4 years<sup>56</sup> and for some it may exceed 20 years.<sup>101,102</sup> The life span of short-lived cells is approximately three days.<sup>104,123</sup>

## Lymphopoiesis

### Bone Marrow

The bone marrow is a site of vigorous lymphopoiesis. Radioautographic data from rodents indicate that under steady state conditions virtually all marrow lymphocytes are formed *in situ* and that the entire population

of small lymphocytes in the marrow is renewed in three days or less.<sup>68,103</sup>

From a kinetic standpoint lymphopoiesis in the marrow is similar to that in primary lymphoid organs such as the thymus (see below) and the bursa of birds; the turnover rate is high and it is independent of changes in the peripheral lymphoid system, such as the depletion of recirculating lymphocytes<sup>94,119</sup> and continuous irradiation of the spleen.<sup>72</sup>

The fate and function of most marrow lymphocytes are unknown. (1) Some marrow-derived cells are capable of serving as pluripotent stem cells<sup>91</sup>; however, although it has been suggested that such cells have the morphologic characteristics of lymphocytes,<sup>93</sup> this is far from proven. (2) Others act as lymphoid stem cells, migrating to the thymus, the bursa, or its elusive mammalian counterpart, where they become committed to a particular type of immune function (see page 303). (3) Some migrate to peripheral lymphoid structures and serve as a source of antibody-producing cells ("B cells").<sup>97</sup> (4) The vast majority of marrow lymphocytes, however, have no clearly recognized function and are expended randomly. The high rate of thymidine reutilization within the marrow lymphocyte pool suggests that many, if not most, of these cells disintegrate *in situ*, thereby providing the next generation of lymphocytes with building blocks for DNA synthesis.<sup>62</sup>

### Thymus

The epithelial elements of the thymus develop from the ventral region of the third and fourth pharyngeal pouches. In the human fetus, thymic lymphocytes are first seen at nine weeks of gestation, approximately three weeks before they appear in peripheral lymphoid tissues such as lymph nodes and spleen.<sup>78</sup> The origin of these cells has been a matter of debate. Although some workers in the past have considered thymic lymphocytes to be derived directly from thymic epithelial cells,<sup>52</sup> most investigators favor the view that thymic lymphocytes are the progeny of immigrant cells, most likely derived

from hematopoietic tissues such as the bone marrow or fetal liver (page 295).<sup>47</sup> Such sequestration of circulating lymphoid precursor cells by the thymus has been proved in experiments with thymus grafts, radiation chimeras, and parabionts, using cells carrying chromosome markers or radioactive labels.<sup>47</sup> Lymph node and thoracic duct cells do not normally migrate to the thymus.<sup>71</sup>

Like the marrow, the thymic cortex has a high rate of lymphocyte production. Mitotic indices are about 10 times higher than those of subcutaneous lymph nodes and five times higher than those of mesenteric lymph nodes and Peyer's patches, in both rodents and man.<sup>47,95</sup> The mitotic activity of thymic lymphocytes is highest in the neonatal period and decreases subsequently, especially during the period of involution, but always exceeds that of peripheral lymphoid tissues.<sup>47,95</sup>

About 95% of thymic lymphocytes are replaced every three to four days, whereas the remainder appear to be more long-lived (see below).<sup>47,96</sup> Most thymic lymphocytes probably result from a series of reduction divisions within the cortex, starting with larger, more primitive lymphoid cells.<sup>17</sup> The final products of these sequential divisions, estimated to average between six and eight in the rat, move into the medulla, where some may enter the circulation or lymphatic channels.<sup>107,108</sup> A large number (75%) of the primitive precursor cells in the cortex are replaced continually by immigrant stem cells or lymphoid precursor cells at the rate of about 1% per day; the remainder appear to be of intrinsic origin.<sup>47</sup>

In contrast to the intense proliferative activity of cortical lymphocytes, the lymphoid cells in the thymic medulla exhibit little or no mitotic activity<sup>95</sup>; the small proportion of long-lived lymphocytes found in the thymus may be located in the medulla.<sup>93</sup> Medullary lymphocytes also have other distinguishing features, including a richer supply of mitochondria, a few more sacs of endoplasmic reticulum, and a well-developed nucleolus; greater resistance to radiation and cortisone than cortical lymphocytes; and some degree of immunologic competence.<sup>47</sup>

The exact fate of thymic lymphocytes is

not firmly established. A small number of cells migrate to the "thymus dependent areas" of lymph nodes and spleen (page 295) where they serve as progenitors of cells involved in cell-mediated immune responses and as helper cells in antibody production (T cells) (page 295). Since the total number of thymic lymphocytes remains relatively constant, the remaining cells must either die *in situ*<sup>47</sup> or emigrate from the thymus<sup>108</sup> and die elsewhere.

Little is known of the immunologic factors that regulate thymic lymphopoiesis, including the mechanisms that provide proliferative stimuli and those that limit proliferation and differentiation. It is clear, however, that thymic lymphopoiesis is not subject to external feedback mechanisms such as antigenic stimulation, resection of peripheral lymphoid organs, partial thymectomy, or the presence of thymus grafts, either single or multiple.<sup>47</sup>

Chief among the nonimmunologic factors affecting thymic lymphopoiesis are the adrenal corticosteroids. Adrenalectomy or adrenal failure is associated with an increase in thymic size and mitotic activity,<sup>47,65,66,68</sup> whereas the administration of exogenous corticosteroids or procedures that augment the endogenous production of corticosteroids, such as stress, cause thymic atrophy.<sup>63,111</sup> This occurs because of lymphocytolysis, not increased export of cells.<sup>65</sup> Testosterone and estrogens also may cause acute thymic involution, but this effect is not mediated by the adrenal steroids.<sup>47</sup> Other hormones such as growth hormone and thyroxine cause an increase in thymic size.<sup>47</sup>

### *Peripheral Lymphatic Structures*

The main areas of active lymphopoiesis in normal spleen, lymph nodes, and Peyer's patches are the germinal centers of lymphoid follicles. Follicles are found in the subcortical zone of lymph nodes (Fig. 7-4) and in the white pulp of the spleen (Fig. 8-1). The lymphocytes in the compact cuff surrounding the germinal centers (Fig. 7-4) proliferate at a slower rate and are not primarily derived from the cells in the germinal centers.<sup>70</sup>

The development of germinal centers

depends on antigenic stimulation; they do not appear until late in the course of a true primary immune response,<sup>59</sup> and are most characteristically associated with secondary antigenic stimulation<sup>59,60</sup> (see page 317 for definitions of these terms). Thus germinal centers may originate from pre-sensitized cells and may represent sites of rapid proliferation of these elements.<sup>59</sup>

The rate of lymphopoiesis in germinal centers is high, rivaling that of bone marrow and thymus.<sup>70,89</sup> Some germinal center cells migrate from the heavily proliferating portion to the more loosely structured area of the center<sup>82</sup> and into the surrounding lymphoid tissue.<sup>89</sup> It is likely that at least a fraction of these cells differentiates into antibody-producing cells.<sup>112</sup> However, most of the newly formed cells appear to disintegrate *in situ* and their nuclei and other constituents are frequently ingested by monocytes and macrophages, whose production accompanies the intense lymphoproliferative activity ("tingible body macrophages").<sup>70</sup> The role of germinal centers in antibody production will be discussed in a later section (page 315).

Following stimulation with certain (thymus dependent) types of antigens (see page 316), cells found in the paracortical zones of lymph nodes and in the periarteriolar sheaths of the spleen (both of which are "thymus dependent") are also capable of proliferation.<sup>50,83</sup> These cells are involved in antigen recognition (page 316) and, in certain experimental systems, their proliferation appears to precede germinal center development<sup>83</sup> and the proliferation of antibody-producing cells.<sup>232</sup> (See also section on cell cooperation in immune responses, page 316.) Such cells are also involved in cell-mediated immune responses (page 320). The rate of lymphopoiesis in paracortical and periarteriolar areas is, however, much less than that in the follicles.

### Control of Lymphocyte Production

The major factor controlling the total mass of lymphocytes within the body appears to be the amount of exposure to antigen. Thus, germfree animals have much less lymphoid

tissue as compared to non-germfree controls, even though the immune system is intact.<sup>54a,92</sup>

A variety of factors that influence blood lymphocyte concentration have been described and proposed as humoral regulators of lymphopoiesis.<sup>66a,72a,91a</sup> However, induction of lymphocytosis in the blood does not necessarily indicate an increase in lymphocyte production. It may simply reflect a reduced rate of recirculation with a lengthened intravascular sojourn, such as occurs after injection of pertussis vaccine.<sup>105</sup> Injection of serum from irradiated rats into normal rats was shown to stimulate mitosis in lymphoid tissue<sup>86a</sup> but one cannot be certain that neo-antigens were not induced by irradiation. Thus, proof of a humoral factor specifically governing lymphopoiesis is lacking.<sup>117</sup> The influence of adrenal steroids and other hormones on lymphopoiesis has been discussed (page 302).

### The Circulation of Lymphocytes

Two basic migration patterns of lymphocytes have been identified (Fig. 7-8): one involves the migration of precursor cells from the marrow to the thymus and the bursa and from these to the peripheral lymphoid organs, such as the lymph nodes and the spleen; the other consists of a continuous recirculation of highly differentiated lymphocytes derived primarily from the thymus dependent areas of the lymph nodes and the spleen.

#### Circulation of Precursor Cells

(1) There is a steady migration of rapidly dividing cells from the bone marrow to the thymus,<sup>68,71,108</sup> which may function as a "finishing school" for some immunologically immature cells. For other cells the bursa, at least in birds, may function in a similar capacity.<sup>41,120</sup> (2) Thymus-produced cells in turn migrate to peripheral lymphoid structures where they localize in thymus dependent areas (page 295), and probably contribute to the pool of long-lived lymphocytes subserving T cell function (page 295).<sup>20,47,68</sup> The number of cells migrating from the

Fig 7-8 Circulation of lymphocytes. *A*, Circulation of precursor cells. *B*, circulation of highly differentiated cells. See text for details.

thymus to peripheral lymphoid structures increases considerably following antigenic stimulation.<sup>47</sup> (3) In birds the migration of cells from the bursa of Fabricius to peripheral lymphoid organs also has been demonstrated.<sup>120</sup>

### Recirculation of Lymphocytes

The long-lived small lymphocytes found in the blood, the lymphatics, and the peripheral lymphoid organs comprise most of the recirculating pool. Functionally they are identified as T cells (page 295) and reside in the thymus dependent areas (page 295) of lymph nodes and spleen. The output of lymphocytes from the thoracic duct of many species, including man, is far in excess of the number present in the blood.<sup>11</sup> The hypothesis that a continuous recirculation of cells between blood and lymph explains this rapid turnover of lymphocytes in the blood has been confirmed. (1) It was shown that the profound fall in the output of lymphocytes which occurs during chronic drainage of lymph from the thoracic duct of rats could be prevented if the lymphocytes flowing from the thoracic duct fistula were continuously reinfused into the blood.<sup>11</sup> Furthermore, it was shown that profound lymphopenia and a sharp reduction in the output of lympho-

cytes from the thoracic duct occurred when lymphocytes were killed by irradiating blood as it passed through an extracorporeal circuit.<sup>63</sup> (2) More definitively, when labeled thoracic duct lymphocytes were injected intravenously, they were found in the thoracic duct and the intestinal lymph and there was no decrease in grain count.<sup>11,53</sup> (3) In parabiotic rats labeled lymphocytes of one member of a pair can be recovered from the thoracic duct of the other<sup>110</sup>; these lymphocytes could only have come from the blood of the other rat. (4) The experiments of Hall and Morris clearly show that the great majority of small lymphocytes leaving a node in the efferent lymph are neither formed there nor come from the afferent lymph.<sup>81</sup> Thus they must have passed into the node from the blood.

Whether all lymphocytes in thymus dependent areas are circulating continuously and equally is not known; some experiments suggest the existence of two compartments of cells<sup>80</sup>; one that is readily mobilized and the other consisting of cells that recirculate slowly, or that are only withdrawn under conditions of special stress such as chronic lymphocyte drainage.

The passage of lymphocytes from blood to lymph occurs within lymph nodes and the spleen.<sup>80,81</sup> When labeled cells are injected

into the blood, they accumulate in high concentration in the deeper part of the cortex of lymph nodes, in Peyer's patches, and in the white pulp of the spleen around the central arteriole.<sup>60</sup> The adult thymus is completely excluded from this type of recirculation. Labeled cells then enter lymphatic channels and cross postcapillary venules by passing between the tall endothelial cells.<sup>109a</sup> The nature of the special affinity that small lymphocytes and postcapillary venules have for each other is not known. It has been suggested that sugar groupings on the surface of lymphocytes may be involved in accurate homing.<sup>77</sup>

## Lymphocyte Function

The chief function of lymphocytes is the generation of immunity, a complex phenomenon culminating in the synthesis of specific immunoglobulins (antibodies) and the establishment of cellular immunity. These processes are of sufficient importance to clinical hematology to warrant an outline of their main characteristics.

### Antibody Formation

#### Immunoglobulin Structure—

##### General Features<sup>135,139,160,161,180</sup>

The antibody activity of serum and secretions is associated with a heterogeneous

group of proteins collectively known as immunoglobulins. Since the structural and functional diversity of normal antibodies makes an analysis of their physicochemical properties difficult, most of our knowledge concerning immunoglobulin structure is derived from studies of homogeneous populations of "abnormal" immunoglobulins such as myeloma proteins and monoclonal macroglobulins.<sup>169</sup>

Despite their tremendous heterogeneity, all antibodies share certain structural similarities. All consist of a basic subunit composed of four polypeptide chains held together by disulfide bonds (Fig. 7-9). Two have a molecular weight of 53,000 to 75,000, depending on the immunoglobulin class, and are known as heavy (H) chains; the other two have a molecular weight of 22,500 and are known as light (L) chains. On the basis of their general properties (Table 7-2), and the physicochemical and immunochemical features of their constituent H chains, immunoglobulins may be subdivided into five major classes: IgG, IgM, IgA, IgD, and IgE (Table 7-2). The respective heavy chains are designated by the Greek letters  $\gamma$  (IgG),  $\mu$  (IgM),  $\alpha$  (IgA),  $\delta$  (IgD), and  $\epsilon$  (IgE). Within a given class of heavy chains, subclasses have been distinguished by their antigenic characteristics. For instance, there are four subclasses of IgG (page 309).

In contrast only two types of L chains have

been identified,  $\kappa$  and  $\lambda$ . These chains are shared by all classes of immunoglobulins, although the relative amounts of each vary from class to class. However, any given immunoglobulin molecule has either  $\kappa$  or  $\lambda$ , never both.

Each heavy chain is joined to its adjacent light chain by noncovalent forces and a single disulfide bond. The two light-heavy chain pairs of each immunoglobulin molecule are also linked by noncovalent interactions and by neighboring disulfide bonds (usually two) between the heavy chains. Treatment of immunoglobulins with reducing agents breaks the disulfide bonds.

When a 7S gammaglobulin molecule is

treated with papain in the presence of cysteine, three 3.5S fragments result (Fig. 7-10b)<sup>170</sup>; two of these are identical and consist of a light chain and the amino-terminal end of the heavy chain (the Fd fragment of heavy chain); these are referred to as Fab (antigen binding) fragments. The third piece, known as the Fc (crystallizable) fragment, contains the carboxy-terminal half of both H chains, most of the carbohydrate, and the antigens determining class specificity (eg,  $\gamma$ ,  $\alpha$ ,  $\mu$ , etc). The Fc piece mediates fixation of the immunoglobulin molecule to cells (eg, skin, mast cells, lymphocytes, macrophages), placental transfer, and complement fixation. When 7S is treated with pepsin rather than

papain,<sup>139</sup> one large piece with a molecular weight of 100,000 and many small peptide fragments are obtained. The small fragments are derived from a more complete degradation of the Fc portion, whereas the large fragment is found to consist of two Fab fragments joined by disulfide bonds [F(ab)<sub>2</sub>].

*L chains* are composed of 214 amino acid residues.<sup>171</sup> The chains can be viewed as having two looped regions of equal length (Figs. 7-9 and 7-11). The first of these regions

Dr. B. L. Chain  
R. N. T. Chain  
[Signature]

(starting at the amino-terminal end of the chain and including amino acid residues 1 to 107) is referred to as the variable ( $V_L$ ) region, whereas the remainder is referred to as the constant ( $C_L$ ) region.<sup>171</sup> (The subscript L denotes the light chain origin of the region.) The variable half of the chain is so named because its amino acid sequence varies considerably from one immunoglobulin to another, whereas the constant region shows much less variability. Similar regions are found in the *heavy chains*. The chains belonging to the IgG1 class of immunoglobulins have been studied most extensively.<sup>133,136,172</sup> They are composed of 446 amino acid residues and can be viewed as consisting of four separate regions, each containing a loop with an internal disulfide bridge. Comparable to light chains, the first (amino-terminal) region, consisting of about 121 amino acid residues, is the variable portion of the heavy chain ( $V_H$ ), whereas the remaining regions appear to be similar repetitive units and are designated  $C_{H1}$ ,  $C_{H2}$ , and  $C_{H3}$ , beginning with the region next to the variable one. Thus the Fc fragment consists of the  $C_{H2}$  and  $C_{H3}$  homologous regions, whereas the Fab fragment contains the  $V_H$  and  $C_{H1}$  regions of the heavy chain and both regions ( $V_L$  and  $C_L$ ) of the light chain (Fig. 7-10).

The antigen binding sites reside in the amino-terminal half of the antibody molecule, and, more specifically, in its  $V_L$  and  $V_H$  regions.<sup>135,142,161</sup> Both the heavy and the light polypeptide chains are required for antibody activity. Amino acid sequence data have shown that the variable regions of L and H chains contain smaller regions of "hypervariability"<sup>191</sup> that ultimately form the antigen binding site and are responsible for the generation of antibody specificity and diversity.<sup>135,142</sup> For  $V_L$  the hypervariable regions include amino acid positions 24 to 34, 50 to 56, and 89 to 97; for  $V_H$ , positions 31 to 37, 86 to 91, and 101 to 109.<sup>131</sup> It is obvious that even within  $V_H$  and  $V_L$ , the areas of hypervariability are small in comparison to the length of the entire variable regions. Indeed, their name to the contrary,  $V_H$  and  $V_L$

also contain areas of constancy that are thought to maintain the basic tertiary structure of the chain and thereby allow the hypervariable regions to function in antigen binding.<sup>191</sup>

Within the constant region of light chains ( $C_L$ ), certain amino acid substitutions give rise to distinct allotypic markers. When position 191 of  $\kappa$  light chain is occupied by leucine, the InV(1) and InV(2) allotypes result; the valyl residue at this position gives rise to the InV(3) allotype.<sup>181</sup> The antigenicity of these allotypes is expressed only in the intact molecule: cleavage of the  $\kappa$ -chain into its  $V_L$  and  $C_L$  regions results in loss of InV antigenicity.<sup>180</sup>

Structural variations in the amino acid sequence of light ( $\lambda$ ) chains have been noted at two positions, 191 and 154. At position 191 (corresponding to the InV locus of kappa chains), a lysyl residue is associated with the immunochemical classification of Oz (+), arginyl with Oz (-).<sup>137</sup> Lambda chains containing glycine at position 154 have been designated Kern (+) and those containing a serine residue have been designated Kern (-).<sup>143</sup> Neither the Oz nor the Kern antigens are allelic genetic markers, however.<sup>143</sup>

In addition to the InV genetic marker localized to the constant region of kappa chains, over 20 genetic markers are associated with the constant region of  $\gamma$  chains. These markers will be discussed later (page 309).

## IgG

IgG is the major immunoglobulin in man and constitutes about three fourths of the total  $\gamma$  globulins (Table 7-3). The serum concentration varies from 800 to 1600 mg/dl in adults, but the intravascular pool accounts for less than half the total body IgG; about 55% is found widely distributed within the extravascular space. The total body content is in excess of 1 g/kg of body weight.<sup>189</sup> IgG molecules have a half-life of about 21 days and are thus the longest lived immunoglobulins.

On the basis of antigenic determinants within heavy chains of IgG, four isotypic

subclasses of IgG molecules have been identified in normal serum: IgG1 (66%), IgG2 (23%), IgG3 (7%), and IgG4 (4%).<sup>165</sup> These antigenic differences are the result of variations in amino acid sequences of the carboxy-terminal parts of  $\gamma$ -chains. All four types of molecules are found in any given normal serum, but individual molecules contain only a single type of  $\gamma$ -chain. Similar distributions are found among myeloma proteins.<sup>165</sup> Since these antigenic (isotypic) differences among IgG molecules carry functional implications (see below), they are of more than serologic interest.

In addition to the antigenic differences that determine immunoglobulin subclasses, proteins within each IgG subclass possess distinctive allotypic antigens known as Gm factors. (The corresponding antigens on IgA molecules are known as Am factors.<sup>165,180</sup>) These factors are the products of allelic genes that are associated with the separate cistrons controlling each immunoglobulin subclass.<sup>139</sup> Table 7-4 lists the common markers associated with the IgG1, IgG2, IgG3, and IgA2 subclasses. The IgG4 subclass has no recognized Gm markers.

#### Biologic Properties of IgG

Most of the antibodies developing in secondary responses (page 317) to antigen are

IgG. It is the only immunoglobulin selectively transferred across the placenta, thereby giving a measure of protection to the newborn infant.<sup>162,190</sup>

Some biologic properties of IgG proteins, and particularly those mediated by the Fc fragment, are distinctly subclass specific. Thus complement activation through binding of C1q, the first activated component of complement (page 333), is most efficient with IgG1 and IgG3. IgG2 also is active but IgG4 proteins are completely inactive.<sup>150,163</sup> The binding to macrophage and granulocyte Fc receptors is most efficient with IgG1 and IgG3.<sup>125,146,156</sup> The latter reaction is of importance in opsonization (Chapter 8). Anti-immunoglobulin antibodies (rheumatoid factors) react most readily with IgG1, IgG2, and IgG4 proteins, but not with IgG3 proteins.<sup>165</sup> This reaction appears to be due to the presence of a site called Ga which is found on all subclasses except IgG3. IgG3, on the other hand, has shown a great tendency to aggregation,<sup>132</sup> which is probably involved in its affinity for C1q.<sup>163</sup> Aggregation of IgG3 may also lead to clinically significant hyperviscosity states.<sup>132</sup> In addition, IgG3 is selectively retained in the sera of a number of patients with generalized hypogammaglobulinemia.<sup>523</sup>

Some antibody activities are subclass specific. Thus anti-Rh antibodies are usually

IgG1 or IgG3 (Chapter 27), antifactor VIII antibodies (Chapter 38) are often restricted to IgG4, and other antibodies, such as anti-dextran and antilevan, have been found to be IgG2.<sup>165</sup>

## IgA

The IgA class of antibodies can be divided into two separate systems of immunoglobulins.<sup>129,186</sup> One of these provides IgA antibodies for the *circulation* and the *internal*

secretions such as the aqueous humor of the eye, the cerebrospinal fluid, and the synovial, amniotic, pleural, and peritoneal fluids. It is likely that these IgA antibodies are synthesized by plasma cells of organs normally involved in antibody production. The other system of IgA antibodies is found in *external* secretions such as saliva, tears, bile, colostrum, as well as those of the respiratory tract, the gastrointestinal tract, the seminal vesicles, the cervix, and the urinary tract. The IgA of external secretions is, for the most part, not derived from blood, but is produced locally by plasma cells situated in close proximity to the epithelial mucosa.<sup>186</sup> It is the predominant immunoglobulin in external secretions, although smaller amounts of IgM and IgG may also be found.

In the serum the IgA molecule usually is present as a monomer with a molecular weight of 170,000 and a sedimentation coefficient of 7S, but 9S, 11S, and 13S polymers frequently occur. Its serum concentration is in the range of 200 to 300 mg/dl with a  $t_{1/2}$  of six days.<sup>180</sup> On the basis of antigenic differences within the  $\alpha$  (heavy) chain, IgA globulins can be divided into two subclasses: IgA1 (93%) and IgA2 (7%).<sup>139</sup> In the IgA2 subclass the H-L bond may not be of the disulfide variety, since light chains are liberated in acid, frequently in the form of dimers.<sup>139</sup> The last observation suggests that the L chains may be situated close to each other, perhaps on the inside of the molecular crotch.

Secretory IgA is a large molecule with a molecular weight of 390,000 to 400,000 and a sedimentation coefficient of 11S.<sup>185</sup> It generally consists of a dimer of two IgA molecules and an additional nonimmunoglobulin component known as *secretory piece* or *transport (T) piece*.<sup>186</sup> This component has a molecular weight of 58,000 and is structurally and genetically unrelated to immunoglobulins.<sup>186</sup> The secretory piece is made in epithelial cells rather than in plasma cells and appears to link up with IgA molecules during their transport across the mucosa or within secretions.<sup>185</sup> The function of the secretory

piece is not clear. It appears to have no role in IgA transport,<sup>186</sup> but it may stabilize the molecule and may protect it against proteolysis within secretions, especially those of the intestinal tract.<sup>186</sup>

Another polypeptide chain, designated the *J* chain ("joining" chain), has been detected in association with polymeric forms of serum and secretory IgA, as well as with the IgM pentamer (see below).<sup>145, 157, 158</sup> This chain has a molecular weight of 23,000 to 26,000. It is attached to IgA or IgM polymers by disulfide linkages. Only one *J* chain is found per polymer and none is found in association with monomeric immunoglobulins.<sup>158</sup> It is not detectable by antisera while the polymers are in their native state, but it becomes readily accessible if the polymers are dissociated.<sup>152</sup> In contrast to the secretory piece, *J* chains are produced by plasma cells,<sup>167</sup> and they appear to play a key role in the process of polymerization of immunoglobulin.

### Biologic Properties of IgA

Secretory IgA activity against a variety of viruses and bacteria has been reported,<sup>151, 178</sup> but the mechanism of antimicrobial or antiviral action of IgA is unknown. Although IgA is incapable of fixing complement or acting as an opsonin, the secretory IgA molecule together with complement and lysozyme, an enzyme found in all external secretions so far examined, is capable of killing *E. coli*.<sup>129</sup> The effects of IgA lack are described in Chapter 44. It is rather surprising that most deficient individuals appear to be rather healthy and not overly susceptible to upper respiratory infections. IgA antibodies against intrinsic factor have been reported in the gastric secretion of a patient with pernicious anemia.<sup>144</sup>

### IgM

IgM antibodies<sup>159, 172</sup> are proteins with a molecular weight of 850,000 which sediment predominantly at 18S to 19S, but also at 22S, 26S, and 35S. Because of their size, IgM

molecules are referred to as *macroglobulins*. Their rate of synthesis is only one twentieth that of IgG, whereas their fractional catabolic rate is two to three times that of IgG.<sup>189</sup> This accounts for the relatively short survival ( $t_{1/2} = 5$  days) and low serum levels (80 to 90 mg/dl) of IgM.<sup>159</sup>

IgM macromolecules are composed of five identical subunits called IgM monomers, each of which consists of two  $\mu$  (heavy) chains and two light chains. The light chains may be  $\kappa$  or  $\lambda$  and appear to be identical to those of other immunoglobulins. The heavy chains, on the other hand, have some unique structural features<sup>172</sup>; whereas human  $\gamma$ -chains vary in length from 446 to 450 amino acid residues,  $\mu$ -chains contain in excess of 500 residues and have a correspondingly higher molecular weight of about 70,000. In addition  $\mu$ -chains appear to consist of a variable region and four constant regions, in contrast to the three constant regions of  $\gamma$ -chains. Similarly to  $\gamma$ -chains, however, each region (constant and variable) contains a loop of about 60 amino acids with an internal disulfide bridge flanked on either side by about 20 amino acids. Carbohydrates account for 10.7% of the molecule by weight and are distributed over five sites within the constant region: one within the Fd region, one in the hinge region, two within Fc, and one near the COOH terminus.<sup>172</sup> They affect the conformation and other properties of the molecule but do not contribute directly to antibody specificity. None of the glycopeptides of  $\mu$ -chains corresponds to the single glycopeptide of  $\gamma$ -chains. Finally, the variable regions of  $\mu$ - and  $\gamma$ -chains are much more similar (homologous) than are their constant regions. On the basis of these observations it has been suggested that two genes may code for each immunoglobulin heavy chain; one codes for the variable region and possibly for the same antibody specific site of  $\mu$ - and  $\gamma$ -chains, and the other codes for the constant regions of each chain.<sup>172</sup> At least two subclasses of IgM have been identified on the basis of antigenic differences within the  $\mu$ -chain (IgM1, IgM2).<sup>138, 139</sup> The exist-

## IgA

The IgA class of antibodies can be divided into two separate systems of immunoglobulins.<sup>129,186</sup> One of these provides IgA antibodies for the *circulation* and the *internal*

secretions such as the aqueous humor of the eye, the cerebrospinal fluid, and the synovial, amniotic, pleural, and peritoneal fluids. It is likely that these IgA antibodies are synthesized by plasma cells of organs normally involved in antibody production. The other system of IgA antibodies is found in *external* secretions such as saliva, tears, bile, colostrum, as well as those of the respiratory tract, the gastrointestinal tract, the seminal vesicles, the cervix, and the urinary tract. The IgA of external secretions is, for the most part, not derived from blood, but is produced locally by plasma cells situated in close proximity to the epithelial mucosa.<sup>186</sup> It is the predominant immunoglobulin in external secretions, although smaller amounts of IgM and IgG may also be found.

In the serum the IgA molecule usually is present as a monomer with a molecular weight of 170,000 and a sedimentation coefficient of 7S, but 9S, 11S, and 13S polymers frequently occur. Its serum concentration is in the range of 200 to 300 mg/dl with a  $t_{1/2}$  of six days.<sup>180</sup> On the basis of antigenic differences within the  $\alpha$  (heavy) chain, IgA globulins can be divided into two subclasses: IgA1 (93%) and IgA2 (7%).<sup>139</sup> In the IgA2 subclass the H-L bond may not be of the disulfide variety, since light chains are liberated in acid, frequently in the form of dimers.<sup>139</sup> The last observation suggests that the L chains may be situated close to each other, perhaps on the inside of the molecular crotch.

Secretory IgA is a large molecule with a molecular weight of 390,000 to 400,000 and a sedimentation coefficient of 11S.<sup>185</sup> It generally consists of a dimer of two IgA molecules and an additional nonimmunoglobulin component known as *secretory piece* or *transport (T) piece*.<sup>186</sup> This component has a molecular weight of 58,000 and is structurally and genetically unrelated to immunoglobulins.<sup>186</sup> The secretory piece is made in epithelial cells rather than in plasma cells and appears to link up with IgA molecules during their transport across the mucosa or within secretions.<sup>188</sup> The function of the secretory

piece is not clear. It appears to have no role in IgA transport,<sup>186</sup> but it may stabilize the molecule and may protect it against proteolysis within secretions, especially those of the intestinal tract.<sup>186</sup>

Another polypeptide chain, designated the *J* chain ("joining" chain), has been detected in association with polymeric forms of serum and secretory IgA, as well as with the IgM pentamer (see below).<sup>145,157,158</sup> This chain has a molecular weight of 23,000 to 26,000. It is attached to IgA or IgM polymers by disulfide linkages. Only one *J* chain is found per polymer and none is found in association with monomeric immunoglobulins.<sup>158</sup> It is not detectable by antisera while the polymers are in their native state, but it becomes readily accessible if the polymers are dissociated.<sup>152</sup> In contrast to the secretory piece, *J* chains are produced by plasma cells,<sup>167</sup> and they appear to play a key role in the process of polymerization of immunoglobulin.

### *Biologic Properties of IgA*

Secretory IgA activity against a variety of viruses and bacteria has been reported,<sup>151,178</sup> but the mechanism of antimicrobial or antiviral action of IgA is unknown. Although IgA is incapable of fixing complement or acting as an opsonin, the secretory IgA molecule together with complement and lysozyme, an enzyme found in all external secretions so far examined, is capable of killing *E. coli*.<sup>126</sup> The effects of IgA lack are described in Chapter 44. It is rather surprising that most deficient individuals appear to be rather healthy and not overly susceptible to upper respiratory infections. IgA antibodies against intrinsic factor have been reported in the gastric secretion of a patient with pernicious anemia.<sup>144</sup>

### *IgM*

IgM antibodies<sup>159,172</sup> are proteins with a molecular weight of 850,000 which sediment predominantly at 18S to 19S, but also at 22S, 26S, and 35S. Because of their size, IgM

molecules are referred to as *macroglobulins*. Their rate of synthesis is only one twentieth that of IgG, whereas their fractional catabolic rate is two to three times that of IgG.<sup>189</sup> This accounts for the relatively short survival ( $t_{1/2} = 5$  days) and low serum levels (80 to 90 mg/dl) of IgM.<sup>159</sup>

IgM macromolecules are composed of five identical subunits called IgM monomers, each of which consists of two  $\mu$  (heavy) chains and two light chains. The light chains may be  $\kappa$  or  $\lambda$  and appear to be identical to those of other immunoglobulins. The heavy chains, on the other hand, have some unique structural features<sup>172</sup>; whereas human  $\gamma$ -chains vary in length from 446 to 450 amino acid residues,  $\mu$ -chains contain in excess of 500 residues and have a correspondingly higher molecular weight of about 70,000. In addition  $\mu$ -chains appear to consist of a variable region and four constant regions, in contrast to the three constant regions of  $\gamma$ -chains. Similarly to  $\gamma$ -chains, however, each region (constant and variable) contains a loop of about 60 amino acids with an internal disulfide bridge flanked on either side by about 20 amino acids. Carbohydrates account for 10.7% of the molecule by weight and are distributed over five sites within the constant region: one within the Fd region, one in the hinge region, two within Fc, and one near the COOH terminus.<sup>172</sup> They affect the conformation and other properties of the molecule but do not contribute directly to antibody specificity. None of the glycopeptides of  $\mu$ -chains corresponds to the single glycopeptide of  $\gamma$ -chains. Finally, the variable regions of  $\mu$ - and  $\gamma$ -chains are much more similar (homologous) than are their constant regions. On the basis of these observations it has been suggested that two genes may code for each immunoglobulin heavy chain; one codes for the variable region and possibly for the same antibody specific site of  $\mu$ - and  $\gamma$ -chains, and the other codes for the constant regions of each chain.<sup>172</sup> At least two subclasses of IgM have been identified on the basis of antigenic differences within the  $\mu$ -chain (IgM1, IgM2).<sup>135,139</sup> The exist-

Fig 7-12. Tentative structure of IgM pentamer. See text for details

ence of genetic polymorphism of the  $\mu$ -chains remains to be established

In the intact IgM molecule five monomers are assembled in a star-shaped configuration, the carboxy-terminal ends (Fc pieces) being joined at the center through disulfide bonds, while the antigen binding sites (Fab pieces) extend toward the periphery (Fig. 7-12). The molecule appears to have a great deal of rotational freedom and, while bound to particulate antigen, may take on the appearance of a spider, its legs (Fab pieces) extending toward the plane of the antigen (eg, a cell surface) while its body, consisting of closely linked Fc fragments, protrudes from the center and is ideally suited for other functions, such as complement fixation (page 333).

Since the IgM molecule consists of five subunits, each with two antigen combining sites, 10 combining sites per IgM pentamer would be predicted. Usually this is indeed the case, especially when the antigen is relatively small.<sup>159</sup> However, with some antigens, only five combining sites per IgM molecule can be demonstrated, presumably because half the combining sites are blocked.<sup>139,159</sup>

A single J chain (page 311) has been found attached to the IgM pentamer by disulfide

bridges.<sup>157</sup> IgM monomers do not have J chains.

### *Biologic Properties of IgM*

Macroglobulins are restricted predominantly to the intravascular pool.<sup>159</sup> Little, if any, IgM crosses the placental barrier and most that is present at birth is of fetal origin.<sup>268</sup> Detectable levels of IgM may be synthesized by the human fetus as early as the twentieth week of gestation,<sup>140</sup> but high levels of IgM at birth are usually indicative of intrauterine sepsis.<sup>182</sup>

On cell surfaces a single molecule of IgM readily fixes complement (page 334), whereas antibody doublets are required for fixation by IgG.<sup>159</sup> However, although IgG is efficient at 4° and 37° C, IgM is very inefficient at the lower temperature.

Specific receptor sites on macrophages for the Fc region of IgM have been described in animal systems.<sup>154</sup> Such receptors may play a critical role in the process of phagocytosis of immune complexes.

Generally speaking, IgM antibodies are the first ones to be produced in a primary immune response (page 317), to be replaced

subsequently by IgG antibodies (page 317). In addition, however, certain types of antibody responses remain predominantly IgM, including those against lipopolysaccharide antigens such as the heterophil (Forssman) and Wassermann antibodies, isohemagglutinins, cold agglutinins, and antibodies to the O antigens of gram-negative bacteria.<sup>155</sup>

The role of macroglobulins in plasma cell dyscrasias is discussed in Chapters 52 and 53.

### *IgM Monomer*

Naturally occurring 7S to 8S IgM monomers have been identified in normal sera.<sup>159</sup> Higher concentrations of monomers also occur in various disease states, including systemic lupus erythematosus, Waldenstrom's macroglobulinemia (Chapter 53) and other hypergammaglobulinemic states, congenital rubella, and immune deficiency disorders such as ataxia telangiectasia and "dysgammaglobulinemia."<sup>130,153,179</sup> In some instances IgM monomers have been found to possess antibody activity against blood group substances<sup>183</sup> or cell nuclei ("antinuclear factors").<sup>175</sup> IgM monomers may be related to more primitive immunoglobulins and would appear to be synthesized as such, rather than to represent an *in vivo* or *in vitro* breakdown product of IgM.<sup>179</sup>

### *IgD*

This immunoglobulin is found in low concentration in normal serum (0.3 to 40 mg/dl),<sup>176</sup> and even in IgD myeloma the characteristic spike is frequently absent (Chapter 52). It consists of two heavy ( $\delta$ ) chains and two light ( $\kappa$  or  $\lambda$ ) chains, has a molecular weight of 180,000, and sediments at 7S.<sup>180</sup> It appears to be catabolized rapidly ( $t_{1/2} = 2.8$  days),<sup>174</sup> is confined largely to the intravascular space,<sup>174</sup> and does not cross the placental barrier.<sup>176</sup> Little is known of its fine molecular structure or its functional significance.

### *IgE*

Reaginic antibodies, which mediate acute and sometimes life-threatening allergic reactions in atopic patients, belong to this distinct immunoglobulin class.<sup>128,148</sup> IgE molecules also have two heavy ( $\epsilon$ ) chains and two light ( $\lambda$  or  $\kappa$ ) chains. They have a molecular weight of 200,000, a sedimentation coefficient of 8.2S, and contain 10.7% carbohydrate.<sup>148</sup> Their survival in the serum is shorter than that of any other immunoglobulin ( $t_{1/2} = 2.4$  days), and their serum concentration is in the range of 0.01 to 0.07 mg/dl, with a mean of 0.03 mg/dl.<sup>128</sup> Higher concentrations may be found in the sera of patients suffering from asthma, hayfever, eczema, the Wiskott-Aldrich syndrome (Chapter 44), and helminthic infections.<sup>128,148</sup> IgE-forming plasma cells are most frequent in the respiratory, gastric and intestinal mucosa and in the regional lymph nodes, but few are found in the spleen and in other lymph nodes.<sup>148</sup> Thus IgE, like IgA, is classified as a secretory immunoglobulin.

### *Biologic Properties of IgE<sup>128,148</sup>*

IgE antibodies are capable of sensitizing basophils and mast cells (Fig. 7-13). The Fc portion of the IgE molecule fits into specific receptor sites on the cell surface.<sup>149</sup> When bivalent or multivalent antigens bind to at least two adjacent IgE molecules, the mast cell is triggered to release vasoactive substances, especially histamine and the slow reacting substance of man,<sup>149,166</sup> which in turn are responsible for clinical manifestations such as wheal and flare reactions, bronchospasm, small vessel dilatation, and shock.<sup>149</sup> In addition to its nuisance function in allergic states, IgE may also play a part in normal body defense mechanisms (Chapter 44).

### *Induction of Antibody Synthesis*

ANTIGENS AND IMMUNOGENICITY.<sup>205</sup> Antigens are molecules capable of inducing an

Fig 7-13 Schematic diagram of IgE mediated allergic reaction. Histamine release by mast cells is due to bridging of at least two cell-bound IgE antibodies by antigen, illustrated in (a), b and c cannot trigger histamine release

immune response. Haptens are molecules that are not inherently immunogenic, but that may elicit specific immune responses when they are bound to suitable carrier molecules, which must be immunogenic of their own accord. Hapten specific antibodies, once formed, are capable of combining with the hapten in the absence of the carrier. Haptens, on the other hand, are incapable of eliciting cellular immune phenomena (page 320).

The factors that control the immunogenicity of various antigens are incompletely understood, but several observations are clearly of importance: The ability to respond immunologically to some (if not all) antigens appears to be genetically determined.<sup>231</sup> This can be shown most clearly in animal models, but is undoubtedly also true for man. The genetically determined control mechanisms appear to be expressed at the level of T cell functions (page 316).<sup>232</sup> The physical state of the antigen is also important; the most powerful antigens such as bacteria, viruses, and cells are particulate, whereas soluble proteins are notoriously less effective antigens and are, indeed, highly suitable for the induction of immunologic tolerance (page 331).<sup>205</sup> Manipulations of antigens that increase their capture by the reticuloendothelial system, such as heat aggregation or alum precipitation, also increase antibody production.<sup>205</sup> This suggests that, for some antigens, the

interaction of antigen with macrophages or other phagocytic cells may constitute a necessary first step in the immune response (Fig. 7-14).

**FATE OF ANTIGEN AND ROLE OF MACROPHAGES.** Immunocompetent organs, such as the spleen and lymph nodes, process degradable antigens in two main ways.<sup>221, 236, 266</sup> The greater part of the material is phagocytosed by macrophages within the marginal zone or the medulla and is subjected to degradative enzymes within phagocytic vacuoles and lysosomes, while some is retained in unaltered form, especially at the cell surface. The smaller proportion of antigen is trapped in the lymphoid follicles of lymph nodes, spleen, and Peyer's patches, primarily on the surface of dendritic reticular cells, and is held there for prolonged periods of time. This process is greatly augmented in the presence of specific antibody.

There still is some controversy concerning the role of macrophages and other phagocytic cells in the induction of immunity. Generally speaking, as discussed elsewhere (Chapter 8) macrophages may subserve three types of functions<sup>266</sup>: (1) the removal of antigen from extracellular fluids, (2) the concentration and presentation of antigens to T and B cells, and (3) the change of antigen by degradative processes. The degree to which

these functions influence the immune response depends on many factors, including the type and amount of antigen and the anatomic site at which antigen arrives. For soluble antigens, for instance, macrophages are important for the removal of excess antigen which may lead to an ineffective immune response or tolerance,<sup>266</sup> and for presenting it in concentrated form to other cell types such as T and B lymphocytes.<sup>219,266</sup> For tissue or cell antigens, on the other hand, there is no need for antigen removal or concentration, since the antigen is already being presented in a readily accessible form and on a cell surface; lymphocytes can easily interact with such antigens in the absence of macrophages.<sup>266</sup> For particulate antigens such as bacteria and foreign red cells, both their removal and their concentration appear to be important while their partial degradation

may lead to an improved immune response.<sup>215,220,266</sup> Macrophages may also have the ability to form a highly immunogenic complex consisting of RNA and fragmented antigen ("superantigen") which is capable of inducing antibody formation in lymphoid cells.<sup>221,222</sup> Most of the evidence gives the RNA a carrier rather than an informational role.<sup>221</sup>

The binding of antigen to dendritic reticular cells appears to be enhanced by the presence of "opsonins" early in the primary immune response and by specific antibody subsequently.<sup>224</sup> The antigen is then transported from the outer cortex or marginal zone to the germinal centers by mechanisms that are not yet clear.<sup>224</sup> As lymphocytes move in and out of follicles they come into intimate contact with the deposited antigen and are triggered into blast transformation.<sup>236</sup>

Fig. 7-14. Schematic representation of two mechanisms suggested for the interaction between T and B lymphocytes. A. Direct presentation of antigen by T cells to B cells. B. Specific antibody (IgT) is produced by T cells and is bound to macrophages or dendritic cells. B cells interact with antigen bound to "cytophagic" IgT on the surface of macrophages or dendritic cells. (Adapted from Feldman<sup>218</sup>)

Dr. N. T. Medical College  
UDAIPUR [Raj.]

This mechanism may not play a part in the initiation of early primary immune responses characterized by IgM antibodies, but may act as part of the amplification system characteristic of the secondary (IgG) response.<sup>224</sup>

**THE ROLE OF LYMPHOID CELLS IN ANTIBODY PRODUCTION.** For most antigens the next step in the humoral immune response appears to require the active cooperation of at least two functionally different types of lymphoid cells.<sup>226,232,234,248</sup> The two co-operating cell types have been termed antigen reactive cells (ARC) and antibody forming cells (AFC). The antigen reactive cells are thymus derived (T cells) whereas the antibody producing cells are B cells. The exact nature of T and B cell interaction in antibody production is still incompletely understood, but several important factors have emerged from a large series of studies.<sup>219,226,232,234,243</sup>

(1) Both of these types of cells possess antigen specific receptors, the specificity of which is important in the cooperative effort of these cells. In the case of B cells, these receptors are unequivocally immunoglobulin in nature,<sup>226,239,243,248</sup> but in the case of T cells, evidence for the nature of such receptors has been difficult to obtain. Some studies suggest that these receptors may consist of classically defined immunoglobulin structures,<sup>204,240,250</sup> but it is also possible that they may consist of unique immunoglobulins (IgX) not found freely circulating,<sup>230</sup> or that they may be totally nonimmunoglobulin in nature.<sup>214</sup> Part of the difficulty may be due to the lower concentration of receptors on T cells ( $<10^3$ ) than on B cells ( $10^5$ ).<sup>267</sup> In addition to receptors for antigens, B cells have receptors for the Fc portion of immunoglobulins<sup>240</sup> and for complement.<sup>207</sup> Such receptors are apparently not demonstrable on T cells.

(2) It would appear that (processed) antigen first interacts with thymus derived antigen reactive cells, which are capable of responding to this antigenic stimulation by vigorous mitotic activity, but are incapable of antibody production.<sup>234</sup> In contrast, bone marrow cells, which are a convenient source

of B cells, do not by themselves respond to antigenic stimulation by mitosis. However, following interaction with sensitized T cells, B cells proliferate and differentiate into cells producing large quantities of antibodies.<sup>234</sup>

(3) Both T and B cells have immunologic specificity, but their cooperative effect in antibody production is at least in part due to the fact that they subserve different orders of specificity. This is most clearly evident in the case of antigens that have well-defined carrier and haptenic groups. Thus B cells, which produce antibodies reacting with relatively small determinant groups, appear to interact primarily with haptens, whereas T cells have specificity for aspects of the carrier molecule.<sup>226,243</sup> It has also been shown that effective cooperation between T and B cells occurs only if the hapten and carrier are linked, i.e. are present on the same molecule.<sup>235</sup> These experiments have led to the suggestion that the antigen forms a bridge between T cells, which recognize carrier determinants, and B cells, which recognize and respond to the antibody inducing haptenic determinants. Thus T (helper) cells would serve to present the haptenic determinants to the antibody-producing cells (Figure 7-14).

(4) Under some conditions at least, direct contact between B cells and T cells may not be necessary.<sup>218,219</sup> Following stimulation with antigen *in vitro*, T cells may elaborate a molecule (IgT) that has the characteristics of an IgM monomer, binds antigen, and is strongly cytophilic for macrophages. IgT apparently binds to specific sites on the surface of macrophages, presumably via an Fc receptor, and presents to the passing B cells a carpet of antigen, held in place by the Fab pieces of the IgT molecule. In addition, T cells produce a number of nonspecific mediators which may augment proliferation of B cells and may influence the class of antibody secreted.<sup>218</sup>

(5) It must be noted that T and B cell cooperation is not invariable, since some antigens are capable of stimulating B cells directly. Such antigens are termed thymus independent and include pneumococcal polysaccharide, polymerized flagellin of *Sal-*

monella adelaide, E. coli polysaccharide and polyvinylpyrrolidone.<sup>226</sup> They usually consist of large polymeric molecules with identical repetitive determinants, whose structure may mimic the "carpet of antigen" on the surface of macrophages described previously. Generally speaking, thymus independent antigens only elicit IgM antibody responses.<sup>226</sup>

(6) In addition to their effect on the induction of antibody synthesis by B cells, stimulated T cells also influence several other areas of B cell function. These include the switch from IgM to IgG antibodies (see below), the change of antibody affinity with time,<sup>226,233</sup> and the activity of histocompatibility linked genes that determine immunologic responsiveness to certain antigens.<sup>231</sup> In addition, activated T cells may, under some conditions, be inhibitory rather than stimulatory and may therefore have a fundamental regulatory function in the immune response.<sup>226</sup>

### Antibody Synthesis

Following their interaction with macrophages and T cells (see above) antigen-stimulated B cells undergo a series of cell divisions which greatly increase the number of cells capable of producing specific antibodies.<sup>229</sup> Some of these cells differentiate into mature plasma cells which are highly specialized for antibody production but are no longer capable of division.<sup>209,229</sup> Eventually these cells die and have to be replaced by newly differentiated cells. This process requires the continuing presence of antigen.<sup>264</sup> If antigen is no longer available, the clon of proliferating cells will regress and antibody production will decrease.

Antibodies are synthesized in various lymphoid organs, depending to a large extent on the antigen's portal of entry<sup>264</sup>: in regional lymph nodes following intradermal or subcutaneous stimulation; in the spleen and sometimes in the bone marrow and the lung following intravenous injections; and in the subepithelial lymphoid tissues when antigen penetrates the gastrointestinal or respiratory mucosa.

### Heterogeneity of Antibody Production

Most antigens lead to the production of very heterogeneous populations of antibodies involving different classes of immunoglobulins, variations in affinity, and differences in specificity.<sup>255</sup>

In addition, all of these features may change with time, the direction of change depending in part on the type of antigen involved, the amount available, and whether the stimulus is repeated or not. In many instances, however, the changes follow predictable patterns.<sup>264</sup> In the case of particulate antigens, the *primary response*\* consists of 19S antibodies that are formed very early and may eliminate any remaining antigen. Serum antibody may appear as early as eight to 16 hours after intravenous immunization<sup>260,264</sup> but more commonly after two to four days. The concentration of antibody increases rapidly, and may double every six to 15 hours, depending in part on the dose of the antigen.<sup>264</sup> Thus 19S response generally peaks at about a week and is short-lived (Fig. 7-15). It is relatively resistant to radiation and 6-mercaptopurine but is sensitive to lymphocyte depletion procedures.<sup>264</sup> In comparison to particulate antigens, soluble antigens such as diphtheria toxoid lead to negligible or low concentrations of 19S antibodies.<sup>264</sup>

If the immunizing dose of antigen is sufficiently large, 7S antibodies may appear four to seven days after primary immunization; low doses of antigen, even when particulate, may result in 19S responses only. This primary 7S response may occur with particulate and with soluble antigen and is characterized by a slower rise in antibody titer (Fig. 7-15), but is of longer duration (months or even years). The 7S response is sensitive to x rays, especially before antigen is given, is inhibited by 6-mercaptopurine, and is sensitive to lymphocyte depletion procedures.<sup>264</sup>

If a second dose of antigen is given several weeks or months after the initial stimulus, a *secondary antibody response*\* is seen (Fig.

\* A *primary immune response* is one that results from the first encounter between an antigen and the immune system; the response that occurs after an appropriately spaced second encounter is referred to as a *secondary or anamnestic response*.

Fig 7-15 Primary ( $19S$ ) and  $7S$  immune responses to the phage  $\phi X$  in the guinea pig. Representative responses to injections of  $10^{11}$ ,  $10^9$ , or  $10^8$   $\phi X$  are shown. A  $7S$  response is detected only with larger doses of  $\phi X$  (From Uhr and Finkelstein<sup>264</sup> courtesy of the authors and *Progress in Allergy*.)

7-16)<sup>264</sup> The secondary response can be elicited by very low concentrations of antigen and the latent period for antibody formation is shorter than after the primary stimulus; the initial rise in antibody titers is exponential, and consists almost exclusively of  $7S$  antibodies. After reaching a peak, antibody levels drop rapidly at first, but then reach a plateau which persists for long periods of time. The secondary response is radioresistant, 6-mercaptopurine insensitive, and not affected by lymphocyte depletion maneuvers.

The term "immunologic memory" is used to describe the capacity to produce a secondary antibody response.<sup>264</sup> Immunologic memory must of necessity be a function of long-lived cells. Earlier experiments attributed memory entirely to the long-lived  $T$  cells,<sup>11,13</sup> but it is now known that both  $T$  cells and some  $B$  cells are capable of expressing specific immunologic memory.<sup>226,233</sup> Such  $B$  cells pre-

sumably form part of the pool of long-lived recirculating cells and are unlike the short-lived  $B$  cells described previously (page 299).

### Functional Heterogeneity of Antibodies<sup>217,256</sup>

Anti-2,4-dinitrophenol antibodies obtained from one bleeding of an individual rabbit have been shown to contain fractions with 10,000-fold differences in binding affinity.<sup>217</sup> The average affinity of specific antibodies tends to increase progressively with time after immunization, a phenomenon termed "maturation of the immune response,"<sup>255</sup> perhaps reflecting selection of cells with higher and higher affinity receptors as the concentration of available antigen drops progressively with time.<sup>255</sup> Cells with high affinity receptors would in turn elaborate antibodies of equally high affinity. From a clinical point of view the maturation of antibody affinity is probably more important than the amount of antibody produced. This is due to the wide range of affinities encountered and the importance of affinity in biologic systems.<sup>225,256</sup> In addition, many *in vivo* immune phenomena offering protection to their host operate at low antigen concentrations. In this situation high affinity antibodies may offer a crucial advantage.

The factors that favor maturation of the immune response include<sup>255</sup> (1) optimum doses of antigen, preferably given as a depot; optimal doses need to be determined for each antigen, but in most clinical situations too much rather than too little has been used, (2) the physical state of the antigen, since aggregated antigens are more immunogenic whereas soluble antigens may render high affinity cells selectively unresponsive; (3) the use of immunologic adjuvants.<sup>200,201</sup> Detailed reviews have dealt with other factors that control antibody synthesis such as genetic factors,<sup>231</sup> antigenic competition,<sup>263</sup> the role of circulating antibody,<sup>264,265</sup> and the effect of  $T$  cells.<sup>226</sup>

### Molecular Aspects of Antibody Biosynthesis

Knowledge regarding the biosynthesis, assembly, and secretion of immunoglobulins has been derived from studies involving normal lymphoid organs, mouse plasmacytomas, human tumors, and cell-free systems.<sup>139,209</sup> The DNA sequences coding for heavy and light chain structures are probably located on different chromosomes, since there is no evidence for linkage between them.<sup>221</sup> The coding sequence and consequent production of ribosomal immunoglobulin are similar or identical to those of other proteins (Chapter 2). In rats and mice the bulk of antibody appears to be made on membrane bound

ribosomes,<sup>268</sup> whereas in at least one human lymphoid line only the L chains are synthesized on membrane bound ribosomes, the H chains being made on free cytoplasmic polyosomes.<sup>254,259</sup> It is likely that immunoglobulin can be synthesized on either free or membrane bound polysomes and that the site of synthesis is determined largely by the availability of a well-developed rough endoplasmic reticulum. This is characteristically present in plasma cells but to a lesser extent in lymphoid cells (page 289).

Heavy and light chains are synthesized separately, the heavy chains on large 270S to 300S polyribosomes composed of 16 to 20 subunits, the light chains on smaller 190S to 200S polyribosomes composed of seven to

Fig. 7-16. Primary (1°) and secondary (2°) antibody responses of rabbits injected once (1°) and twice (2°) with an interval of four weeks between injections (From Dean and Webb, *J Path Bact* 31:89, 1928, as illustrated in *Microbiology*, David et al<sup>214</sup> eds, courtesy of the authors and Hoeber Medical Division, Harper and Row)

eight subunits.<sup>139,209</sup> The size of these poly-somes is such as to suggest synthesis of each chain as a single unit.<sup>139</sup> Under normal conditions, light chains may be synthesized in slight excess.<sup>202,253</sup>

Following separate synthesis of heavy and light chains there may be some assembly of free light chains and ribosome bound heavy chain, but most assembly appears to occur after the release of polypeptide chains from the ribosomes; this may result in the formation of H-L half molecules initially, two of which then combine to form a complete gamma globulin monomer. Intermediate H<sub>2</sub>L and H<sub>2</sub> structures have, however, also been isolated, suggesting that the final H<sub>2</sub>L<sub>2</sub> structure may be reached by several pathways.<sup>209</sup> In most instances polymeric gamma globulins such as IgM (9S) and IgA (9S, 11S, 13S) are assembled intracellularly from their constituent subunits,<sup>209,210</sup> but a few studies suggest assembly at the time of secretion or extracellularly.<sup>211,257</sup> J chain has been detected intracellularly, bound to IgM or IgA polymers.<sup>212</sup>

The attachment of carbohydrate probably begins on the ribosome but, except for glucosamine, is not complete until the protein is released into the cytoplasm.<sup>252,254</sup> The complete or nearly complete immunoglobulin molecule passes to the Golgi zone. There the immunoglobulin molecule attaches to membrane and additional monosaccharides are attached with the aid of appropriate enzymes, so as to form polysaccharide chains. The sugars added include additional glucosamine, galactose, and, finally, sialic acid.

It has been suggested that the carbohydrate moiety facilitates the secretion of immunoglobulins by the cell,<sup>261</sup> but this aspect of antibody production is poorly understood.

Although the synthesis of light chains and heavy chains takes only 30 and 60 seconds, respectively,<sup>139</sup> the addition of carbohydrates and the process of secretion take at least half an hour. Approximately 10<sup>13</sup> molecules (2.2 g) of IgG are synthesized per second in an adult, plus an equal number of other immunoglobulins.<sup>189,258</sup> The distribution and fate of individual immunoglobulins have been discussed previously (Table 7-3).

The vast majority of antibody synthesizing cells contain only one type of heavy chain and one type of light chain,<sup>206,212,213</sup> but a small number of cells (usually less than 1%) contain more than one type of heavy chain, usually  $\mu$  and  $\gamma$ .<sup>213,244</sup> This observation suggests that a single cell might switch from IgM to IgG synthesis during the course of the immune response.<sup>237</sup>

### Cellular Immunity

In addition to their important contribution to antibody production (page 316), thymus derived lymphocytes (T cells) also play a central role in the induction and execution of cellular immunity. Cellular immune phenomena are those that result from the interaction of antigen with sensitized lymphocytes, rather than with humoral antibody. Characteristically, such responses can be transferred passively from a sensitized individual to a nonsensitized one by cells but not by circulating antibody.

Most reactions of cellular immunity develop more slowly than those mediated by antibody, hence the term "*delayed hypersensitivity reaction*" which, in addition to its specific meaning (page 325), frequently is used in a generic sense to include all cellular immune phenomena. Clinically important examples of cellular immunity are listed in Table 7-5.

### Induction of Cellular Immunity

The immunogenicity of antigens and their handling by macrophages are as important in the induction of cellular immunity as in the

**Table 7-5. Clinical Expressions of Cellular Immunity**

-

induction of antibody synthesis. Several factors favor the induction of cellular immunity, including (1) immunization by the intradermal or subcutaneous, rather than the intravenous route<sup>374</sup>; (2) the incorporation of antigen into immunologic adjuvants, which usually contain killed tubercle bacilli in mineral oil<sup>264,312</sup>; and (3), in natural infections, the type of organism involved; generally speaking, intracellular parasites such as mycobacteria, salmonella, brucella, and viruses induce delayed hypersensitivity most readily.<sup>377</sup>

As in the induction of antibody synthesis, macrophage bound or processed antigen is capable of interacting with antigen specific T cells,<sup>266,375</sup> presumably in the paracortical areas of lymph nodes and, to a lesser extent, in the thymus dependent areas of the spleen. In vitro experiments have shown that close contact between macrophages and lymphocytes is essential<sup>294</sup> and may be facilitated by the presence of uropods on T cells (page 287). T cells react with antigen by virtue of specific receptors for single antigenic determinants.<sup>214,251</sup> These small lymphocytes transform into blast-like forms, undergo clonal proliferation, and produce specifically sensitized small lymphocytes.<sup>13</sup> Morphologically this event is reflected in the appearance of pyroninophilic cells in the paracortical areas of draining lymph nodes.<sup>13,20</sup> Lymphocytes not coming into direct contact with antigen may be recruited into the immune response by the release of humoral mediators, such as transfer factor (page 324) and other blastogenic factors produced by sensitized cells (page 323). Some studies suggest that T-T cell interaction occurs during the development of cellular immunity,<sup>226</sup> just as B-T cell interaction is essential for the induction of antibody production (page 316). Within a few days following antigenic stimulation, blast-like cells are seen within the efferent lymph of stimulated nodes.<sup>325,326,327</sup> These cells may migrate to other lymphoid tissues<sup>327</sup> and thereby lead to systemic sensitization.<sup>309</sup> They also act as effector cells in cell-mediated immune responses (see below) and carry immunologic memory<sup>317</sup> (page 318).

## Mechanisms of Cellular Immunity

The properties of sensitized T-cells that are important in the effector arc of cellular immunity (Table 7-4) include the ability to recognize and interact with specific antigenic determinants, the ability to respond to this interaction by further proliferation, the production of soluble mediators of immunity, and the capacity to kill antigen-bearing target cells on contact.

The recognition of antigen by sensitized T cells ("memory cells") is mediated by highly specific receptors,<sup>243,300,383</sup> presumably similar to those found on antigen reactive cells (ARC's) in unprimed individuals (page 316). Under in vitro conditions, antigen-lymphocyte interaction results in transformation and clonal proliferation of sensitized cells.<sup>348</sup> In most instances, lymphocyte transformation correlates with delayed-type hypersensitivity in vivo,<sup>351,354</sup> but exceptions have been noted.<sup>285</sup> In vitro lymphocyte stimulation has illuminated many aspects of cellular immunity, including the need for macrophages in the induction of proliferation in sensitized cells,<sup>283</sup> the high degree of carrier specificity of these reactions,<sup>243,364</sup> and the heterogeneity of cellular immune responses to antigen in vitro, which probably reflects a range of binding affinities of cellular receptors for antigen comparable to that seen in secreted antibodies (page 318).<sup>235,335</sup>

## Humoral Mediators of Cellular Immunity

When sensitized lymphocytes react with antigen in vitro, they elaborate into the culture medium a number of biologically active substances.<sup>296</sup> Many of these substances (Table 7-6) are capable of eliciting inflammatory reactions and, since only a few sensitized lymphocytes can produce enough of these mediators to affect a relatively large number of cells, the whole reaction is amplified greatly.<sup>299</sup> The properties of a number of these substances, derived from supernates of antigen-sensitized lymphocyte cultures and sometimes referred to as *lymphokines*, will be summarized briefly.

**Table 7-6. Humoral Mediators of Immunity**

  - 8 Transfer factor
- 

***Migration Inhibitory Factor (MIF)***

MIF inhibits the migration of normal macrophages out of capillary tubes (Fig. 7-17)<sup>285,296</sup> Although the production of MIF is immunologically specific, the inhibition of macrophages occurs in a random and nonspecific manner, even in the absence of antigen. MIF is a nondialyzable macromolecule with a molecular weight of 35,000 to 55,000; it is a nonimmunoglobulin acidic glycoprotein which is destroyed by chymotrypsin. Its biologic effect is also destroyed by neuraminidase, suggesting that sialic acid residues are necessary for its activity.

***Macrophage Chemotactic Factors (MCF)***<sup>379</sup>

MCF can be differentiated from MIF on the basis of their distinct physicochemical properties. Separate chemotactic factors for lymphocytes, neutrophils, and eosinophils also have been identified,<sup>297</sup> the one for eosinophils requiring antigen-antibody complexes for its elicitation.

***Macrophage Activating Factor***

By present techniques this factor is indistinguishable from MIF.<sup>296</sup> It is produced by sensitized and stimulated T cells and leads

to the "activation" of macrophages.<sup>345</sup> Activated macrophages are larger and more complex morphologically than are ordinary ones. They also have a marked propensity to spread on glass and are more avidly phagocytic. Activated macrophages have an increased content of acid hydrolases, an increased digestive capacity, and an increased mitotic rate. Thus activated macrophages acquire a greater ability to deal with intracellular bacteria and other phagocytosable matter.

Although release of macrophage activating factor is triggered by immunologically specific events, the consequent macrophage activation results in heightened cellular (macrophage-mediated) immunity towards a variety of microorganisms as well as noncellular antigens.<sup>315</sup> Thus, as for MIF, the production of macrophage activating factor is immunologically specific, but its effect is nonspecific.

It is readily apparent how MIF, the chemotactic factor, and the macrophage activating factor might collaborate at an inflammatory site. A specifically sensitized lymphocyte interacts with an appropriate antigen, eg, bacterial, and elaborates all three principles; the chemotactic factor attracts macrophages to the area, MIF confines them to the inflammatory site, while the macrophage activating factor induces an increased capacity to deal with the invading organism.

***Lymphotoxin (LT)***

Cell-free supernatants from lymphocyte cultures stimulated by specific antigen or nonspecific mitogens, such as phytohemagglutinin (page 341) or antilymphocyte serum, contain a substance that is cytotoxic for a variety of target cells in vitro.<sup>318,357</sup> Similar cytotoxic factors are produced by sensitized lymphocytes when stimulated by living or dead viruses,<sup>285</sup> as well as by long-term lymphocyte cultures in the absence of stimulation by antigen or mitogens.<sup>285</sup> Human lymphotoxin is a nonimmunoglobulin protein migrating with the  $\beta$  and  $\gamma$  globulins.<sup>285</sup> It has a molecular mass of 80,000 daltons and is inactivated by heating at 80° C.<sup>318</sup> Its production is inhibited by a variety of metabolic

Fig. 7-17. Quantitative assays of migratory inhibition of macrophages by MIF. The migration of cells from an animal sensitized to DNP-GPA is inhibited only by the DNP-GPA antigen and not by DNP conjugated with another carrier protein (DNP-BGG). With animals sensitized to DNP-BGG, MIF activity is similarly specific, in this instance DNP-GPA produces a "control" result (from David<sup>298</sup> courtesy of the author and Sinauer Associates, Inc.)

inhibitors but its release is probably not closely linked to DNA synthesis.<sup>355</sup>

The cytolytic activity of lymphotoxin is readily demonstrable *in vitro*. There is a wide range of sensitivity to its action among various cells, human lymphocytes being the most resistant and mouse L cells the most sensitive.<sup>285</sup> The amount of lymphotoxin produced *in vivo* may not be sufficient to permit a cytotoxic effect on target cells, however. Its primary *in vivo* effect may be growth inhibition.<sup>285</sup>

Other growth inhibiting factors have been described in supernatants of antigen stimulated cells, including the "cloning inhibitory factor,"<sup>285</sup> the "proliferation inhibitory factor,"<sup>321</sup> and the "inhibitor of DNA synthesis" (IDS).<sup>357</sup>

### Blastogenic Factors

In addition to factors inhibiting growth, various factors that have a stimulatory effect on other lymphocytes are also produced.

They include factors capable of stimulating other lymphocytes in the absence of antigens,<sup>311,359</sup> those requiring antigen,<sup>336,376</sup> and some that allow purified lymphocytes to be stimulated by antigen in the absence of macrophages.<sup>278</sup> Other blastogenic factors make normal lymphocytes cytotoxic for target cells.<sup>311</sup>

### Skin Reactive Factors (SRF)<sup>285</sup>

SRF elicit reactions that resemble delayed-type hypersensitivity responses (page 325), but occur much earlier. The activity mediating this effect has not yet been distinguished from MIF, LT, or blastogenic factors.<sup>399</sup> A factor that results in skin lesions similar to those produced by SRF but that also contains an activity causing changes in vascular permeability has also been extracted from normal or sensitized lymph node cells. This factor has been termed "lymph node permeability factor" (LNPF).<sup>356</sup>

### Immunoglobulin

The synthesis of immunoglobulin by B cells was discussed in an earlier section (page 317). The synthesis of a  $\beta_2$  microglobulin by phytohemagglutinin stimulated lymphocyte cultures and long-term cultures has also been described.<sup>333,348</sup> In addition, it is possible that T cells may be capable of producing small quantities of an immunoglobulin-like factor which has been postulated to play a role in B-T cell interaction (page 316).

### Interferon

Interferons are proteins that confer antiviral resistance on cells that are normally virus susceptible. Agents that stimulate the production of interferon are known as inducers and include a large variety of substances<sup>323</sup> such as viruses; nucleic acids and especially double-stranded RNA; a variety of bacteria and their products including endotoxins and exotoxins; low molecular weight substances such as tilorone, cyclohexamine and kanamycin; and a number of substances that stimulate the proliferation of lymphocytes *in vitro*, including phytohemagglutinin, pokeweed mitogen, and specific antigens such as tuberculin. Although interferon may be produced by virtually all tissues of the body, lymphoid cells, especially T cells, appear to be a major source of interferon production.<sup>285,320,381</sup> Partially purified interferon preparations show a remarkable degree of structural heterogeneity with molecular weights ranging from 20,000 to 40,000 to over 100,000.<sup>323</sup> It has been suggested that human interferon may consist of multimeric aggregates of smaller subunits.<sup>289</sup> The monomer of virus-induced human interferon was found to have a molecular weight of 12,000. Interferon appears to be an unusually stable glycoprotein, but detailed structural studies are not available.

Following induction, the protein is synthesized and released quickly from the cell. This may occur as early as two to four hours after endotoxin, in six to 18 hours with viral in-

ducers,<sup>323</sup> and as late as four days when sensitized cells are stimulated by purified protein derivative (PPD) *in vitro*.<sup>283</sup> Interferon confers antiviral protection on the cell producing these proteins, but also carries the message of imminent danger to neighboring uninfected cells. It has been postulated that the antiviral activity of interferon in these cells is mediated by the synthesis of another protein<sup>314</sup> which, at the ribosomal level, interferes with the synthesis of virus coded enzymes and structural coat proteins necessary for viral replication.<sup>302</sup> Interferons display inhibitory activity against a large number of RNA and DNA viruses,<sup>323</sup> both cytotoxic and oncogenic, as well as a large number of nonviral infectious agents.<sup>323</sup>

### Transfer Factor (TF)<sup>343,347</sup>

In 1942 Landsteiner and Chase discovered that immune responses could be transferred from sensitive to nonsensitive individuals with live lymphoid cells.<sup>342</sup> In 1954, Lawrence demonstrated that delayed hypersensitivity could also be transferred by killed or disrupted cells.<sup>343</sup> Later it was shown that supernatants from specifically stimulated lymphocyte cultures were equally effective, but that cell populations so stimulated lost their ability to transfer responsiveness to the stimulating antigen but not to other sensitivities the patient carried.<sup>343</sup> Thus the sensitizing factor is antigen specific and is not immediately replenished. This curious immunologic phenomenon is mediated by a small molecule, appropriately termed *transfer factor*.<sup>343</sup> It is readily dialyzed and has a molecular weight of less than 10,000. Transfer factor is nonantigenic, nonimmunoglobulin, and relatively heat labile, being destroyed at 56° C for 30 minutes. It appears to be of polypeptide and/or polynucleotide composition but its detailed structure is unknown.

The immunologic sensitivities conferred on the recipient and his circulating lymphocytes are always concordant with those possessed by the donor of transfer factor. Sensitivity to a number of bacterial antigens, fungal antigens, and histocompatibility anti-

gens has been transferred successfully, always with a great degree of immunologic specificity. Results of skin tests are positive to specific antigens and the recipient's lymphocytes respond to antigen *in vitro*. Such sensitivity may last for months or years and may even be transferred from the recipient to other insensitive donors.<sup>343</sup> Transfer factor does not induce antibody production.<sup>343</sup>

It has been postulated that transfer factor may represent a convenient way of rapidly augmenting the number of cells capable of reacting with a specific antigen.

### Lymphocyte Cytotoxicity

Evidence for the ability of lymphocytes to cause tissue damage directly comes from at least four different *in vitro* situations in which target cell destruction could be demonstrated.<sup>285,356</sup> (1) Lymphocytes sensitized *in vivo* or *in vitro* to specific target cell antigens may be cytotoxic for these cells in the absence of demonstrable antibody or complement.<sup>287,292,356,362</sup> (2) Sensitized lymphocytes stimulated by specific antigen, or non-sensitized lymphocytes stimulated by nonspecific mitogens, may exert cytotoxicity on target cells antigenically unrelated to the stimulating agent.<sup>285,356,363</sup> (3) Lymphocytes from nonsensitized individuals may be induced to cause cytolysis of target cells by the presence of antitarget cell antibodies, bound to the target cell.<sup>285,356</sup> (4) Normal lymphoid cells may lyse target cells coated with certain complement components.<sup>356</sup>

The mechanisms of lymphocyte mediated toxicity are poorly understood, but several important principles have been established.<sup>285,356</sup> (1) Although cytotoxicity is mediated by lymphocytes, macrophages and granulocytes may contribute to the killing of target cells. (2) When the reaction involves lymphocytes sensitized to specific surface antigens of target cells, the cytotoxic reaction is exquisitely specific for cells carrying the immunizing antigen, other cells being unaffected. In all other situations, and especially when lymphocytes are activated by unrelated antigens or mitogens, the lymphocytes be-

come nonspecifically cytotoxic for a variety of syngeneic, allogeneic, and xenogeneic target cells. (3) Intimate contact between lymphocyte and target cell is required but this does not exclude the possibility that cytotoxic factors may be produced locally. (4) Lymphocytes have to be alive and metabolically active in order to express cytotoxicity. (5) The correlation between delayed hypersensitivity reactions *in vivo* and specific cytotoxicity for target cells *in vitro* is often excellent, but this does not exclude the participation of other cells from reactions of cytotoxicity.<sup>322,341</sup> (6) In some *in vitro* systems lymphotoxin (page 322) appears to play a crucial role in mediating lymphocyte cytotoxicity, since anti-lymphotoxin antibodies effectively prevent cytotoxicity.<sup>378</sup>

At the present time, *in vitro* models of lymphocyte mediated cytotoxicity provide the most important clues for interpreting a variety of immunologic phenomena of clinical interest, including those of tumor immunity, allograft rejection, and some autoimmune and other phenomena, but much more needs to be learned. Indeed, some mechanisms found *in vitro* may have no corresponding counterpart *in vivo*.<sup>283</sup>

### Clinical Expressions of Cellular Immunity

#### Delayed Hypersensitivity Reactions<sup>282,286,297,374</sup>

When antigens like tuberculin are injected into the skin of sensitized individuals, an area of erythema and induration appears after a lag of several hours and reaches maximal intensity in 24 to 72 hours. Microscopically, this lesion initially is characterized by capillary dilatation and exudation of fluid; by four to six hours a cellular infiltrate is seen which at first consists of polymorphonuclear granulocytes, but by 24 hours these are almost totally replaced by mononuclear cells.

The generation of such cellular infiltrates requires two types of cells: sensitized lymphocytes and macrophages. The initiating event is a reaction between specifically sensi-

tized lymphocytes and antigen that results in the release of a number of soluble mediators. Perhaps the most important of these are macrophage chemotactic factors (page 322) and, especially, MIF (page 322). These factors attract macrophages to the area and immobilize them at the injection site. In a fully developed delayed hypersensitivity reaction at least 95% of the accumulated mononuclear cells are macrophages, and less than 5% of the cells consist of specifically sensitized lymphocytes. The specifically committed lymphocytes accumulating within inflammatory exudates may also be derived from a rapidly dividing population of cells that seems to have a particular propensity for localizing in inflammatory foci.<sup>339</sup> Long-lived lymphocytes appear to be excluded from such areas.<sup>339</sup>

MIF or a closely related factor is also responsible for the activation of trapped macrophages (page 322). These activated macrophages are primarily responsible for the inflammatory features of delayed hypersensitivity reactions, although other factors such as lymphotoxins (page 322) and skin reactive factors (page 323) may play a minor role. Still other factors such as transfer factor (page 324) may serve to amplify weak local reactions by recruiting uncommitted lymphocytes into the pool of specifically sensitized cells, while some of the blastogenic factors (page 323) may aid in their recruitment and proliferation, but this remains to be established.

*Allergic (eczematous) contact dermatitis* is a clinically important example of delayed hypersensitivity reactions. Causal agents are generally small molecular weight compounds such as dyes, cosmetics, topical medications, industrial substances, plastics, and allergenic plant extracts such as those obtained from poison ivy (pentadecylcatechol).<sup>280</sup> Application of one of these substances to the skin of susceptible individuals can lead to sensitization so that a second application of the same chemical a week or more later produces a delayed inflammatory response with all the morphologic characteristics of delayed hypersensitivity reactions.

The mechanisms of sensitization have been elucidated by the use of synthetic contact sensitizers such as dinitrochlorobenzene (DNCB).<sup>306,308,503</sup> DNCB behaves as a true hapten (page 314), being incapable of causing sensitization unless firmly coupled to an immunogenic carrier molecule. The coupling is provided by a variety of proteins within the upper half of the epidermis, to which DNCB residues bind by covalent bonds.<sup>308</sup> Presumably covalent bonding of haptens distorts carrier proteins sufficiently to render them unrecognizable as self and therefore potentially immunogenic. Sensitization is generally dependent on adequate lymphatic drainage from the site of application to the regional nodes.<sup>313</sup> The processes within nodes are similar to those described for other types of cellular immunity (page 321). Sensitized cells then disseminate to other parts of the lymphatic system.

In order to elicit a delayed hypersensitivity response after sensitization, the hapten must again be conjugated with a carrier substance.<sup>307</sup> Such secondary reactions are most readily elicited in skin, but may also occur in mucous membranes.<sup>280</sup> The high degree of carrier specificity of delayed hypersensitivity reactions<sup>28a</sup> requires that structurally similar hapten-protein conjugates be formed on second exposure to the hapten. Contact sensitivity may also be transferred from one individual to another by means of lymphocytes,<sup>291</sup> suggesting that similar families of conjugates are produced by different patients.

### Role of Cellular Immunity in Infection

Cellular immune responses, of which delayed hypersensitivity reactions are a prototype, are of paramount importance in the defense against a number of obligate or facultative intracellular parasites such as viruses, rickettsiae, mycobacteria, *L. monocytogenes*, *Brucella abortus*, *S. typhosa*, and certain protozoa.<sup>345</sup> It is significant that, although secretory or circulating antibodies are capable of inactivating some infectious agents such as viruses and plasmodial parasites during cer-

tain stages of their life cycle,<sup>304,346</sup> and are capable of serving as opsonins for others, they leave many pathogenic bacteria and protozoan parasites quite unaffected, even during the extracellular phases of their existence. More importantly, antibodies and lymphocytes are completely incapable of dealing with infectious agents protectively accommodated within the cytoplasm of phagocytic cells.<sup>345,346</sup> Defense against such organisms obviously depends on measures that alter the intracellular environment from one in which the parasite normally prospers, to one that will not support its continued survival.<sup>346</sup> Such a mechanism is provided by the "activation of macrophages" by a product of sensitized lymphocytes (page 322).

The role of cell-mediated immunity in the control of viral infection is less clearly defined, although its importance is well established.<sup>297,377,382</sup> Lymphocytes do not normally cause virus neutralization,<sup>297</sup> but sensitized lymphocytes readily produce interferon following interaction with the virus (page 324). In addition, virus-infected cells carry new virus-induced antigens (page 329) and cell-mediated immunity may play a role in eliminating or destroying such cells.<sup>297</sup> It is also known that macrophages play a role in preventing the dissemination of virus,<sup>365</sup> and that macrophages from an immune host are more efficient than those from a non-immune one. Whether this increased efficiency is mediated by sensitized lymphocytes, increased interferon production, or some other intrinsic properties of macrophages is not known.

### Allograft Rejection<sup>13,387</sup>

Allograft\* rejection is an immunologic phenomenon, in most instances mediated by sensitized lymphocytes, rather than by circulating antibodies. The role of the latter will be discussed in a subsequent section (see below).

Sensitization is mediated by small recirculating lymphocytes, an unusually large num-

ber of which seem to be precommitted to interact with allogeneic histocompatibility or transplantation antigens.<sup>337</sup> A detailed discussion of human transplantation antigens is found in Chapter 12. Sensitization occurs within the graft (peripherally), possibly at the level of the graft's vascular endothelium,<sup>350,370</sup> or within lymph nodes ("centrally"), which have sequestered antigenic material from the bed of the graft.<sup>281</sup> Sensitization may also be a response to passenger cells, that is, host leukocytes carried over in the vessels of the allografts. Antigen-reactive cells triggered by contact with antigen then become established in thymus dependent areas of lymphoid tissue (page 295), and develop into large blast-like ("pyroninophilic") cells.<sup>301</sup> The proliferative response of these cells, possibly augmented by the recruitment of previously uncommitted cells (page 326), leads to the formation of a large clone of immunologically committed effector cells. This central proliferative response is indispensable to the generation of allograft immunity<sup>13</sup>; it is absent in animals incapable of responding because of effective immunosuppression, tolerance, or histocompatibility.

In man, cell-mediated allograft rejection usually occurs within one or two weeks after grafting.<sup>276</sup> The effector are that leads to the damage and destruction of solid tissue grafts is poorly understood. It appears to involve mononuclear cells, some of which are sensitized T cells, although many have a high mitotic index, even prior to the application of a graft.<sup>316</sup> Sensitized T cells ("killer cells") are capable of destroying graft cells on contact (page 325) without the need for complement or other serum factors,<sup>388</sup> but rejection may also involve the release of cytotoxic factors (page 322) or the biologic activity of activated macrophages (page 322), including the release of lysozymes within the vasculature of the graft.

The mixed leukocyte reaction (Chapter 12) is regarded as an *in vitro* correlate of allograft rejection *in vivo*.

Circulating antibodies may affect allografts in several ways: (1) When the recipient of solid organ grafts has high titers of antibodies

\* Allografts (or homografts) are tissue grafts transplanted from one individual to another of the same species.

directed at graft histocompatibility antigens, a "hyperacute rejection phenomenon" may be seen, usually within minutes of establishing vascular anastomoses.<sup>368,384</sup> This rejection occurs most commonly in kidney allograft recipients who have been presensitized by a prior graft, multiple blood transfusions, or multiple pregnancies. The early lesions are characterized by the accumulation of polymorphonuclear leukocytes and platelets (not lymphocytes) within the microvasculature, with progression to widespread capillary thromboses. Anti-HLA antibodies can be eluted from rejected kidneys<sup>384</sup> and may have triggered the entire reaction<sup>383</sup> which is morphologically similar to the Shwartzman reaction.<sup>368</sup> It has been suggested that high risk patients be treated prophylactically with anticoagulants,<sup>368</sup> but, although such therapy prolongs survival of canine renal allografts, it does not prevent their eventual rejection.<sup>275</sup> Others have attributed hyperacute rejection to intense vasospasm of unknown cause.<sup>303</sup>

(2) A patient in whom a renal allograft has been maintained for a prolonged period of time with the aid of immunosuppressive therapy may develop marked endothelial proliferation within the small vessels of the graft, thickening of the basement membrane, and fibrinoid necrosis of the vessel wall, which may be due to the chronic deposition of anti-allograft antibodies or to the deposition of antigen-antibody complexes along the basement membrane of the vessel walls.<sup>332</sup> Such a patient often develops the nephrotic syndrome. The reaction must be differentiated from the recurrence of renal disease, such as glomerulonephritis, which originally caused the patient's own kidneys to malfunction.<sup>332</sup>

(3) Under some circumstances non-cytopathic anti-graft antibodies may actually protect the graft against the activity of sensitized lymphocytes.<sup>332,359</sup> When such protection involves transplanted tumors, it is known as "immunologic enhancement."<sup>330</sup>

#### Graft-Versus-Host Disease (GvH)

Graft-versus-host disease refers to an immunologically specific phenomenon occur-

ring in an immunoincompetent host who is the recipient of viable, histoincompatible lymphocytes.<sup>284,319,349,366</sup> Most commonly such a reaction is seen in patients who have been rendered immunoincompetent by total body irradiation (in preparation for a bone marrow transplant) or in patients suffering from acquired or congenital immune deficiency syndromes (Chapter 44). In either instance, the patient is incapable of rejecting these histoincompatible cells which localize in lymphoid tissues and proliferate in response to the antigenic stimulation provided by the host's own tissues. In addition, the host's own lymph node cells are stimulated to proliferate extensively,<sup>284</sup> leading to lymphadenopathy and splenomegaly initially, but atrophy, fibrosis, and lymphopenia soon supervene. Other acute changes include evidence of tissue damage elsewhere: severe exfoliative dermatitis and hair loss, hepatitis, diarrhea and gastrointestinal ulcerations, severe wasting and emaciation, and a Coombs'-positive hemolytic anemia.

When the initial GvH reaction is mild, or when appropriate therapy with immunosuppressive drugs is given, the acute changes may regress and the patient (or experimental animal) may lead a relatively normal existence.<sup>315,329</sup> This regression appears to be due to the presence of blocking factors within the serum that prevent the GvH reaction.<sup>329</sup> In most instances, however, the patient succumbs to the acute manifestations of the underlying disease or to late complications, such as infections.<sup>349</sup>

Most of the manifestations of GvH disease, and certainly those that lead to fatal complications, are mediated by cells rather than by antibodies. It appears that interaction between distinct populations of thymus derived cells<sup>372</sup> and/or cooperation between thymus and bone marrow derived cells<sup>279,331</sup> is required for the expression of GvH reactivity.

When histoincompatible lymphocytes are injected under the renal capsule of nonirradiated hosts, a local GvH reaction results that appears to be due to the interaction of host and donor lymphocytes rather than to a direct attack by donor lymphocytes on kidney

cells.<sup>309</sup> Thus in some situations, at least, parenchymal cells may be damaged nonspecifically as "innocent bystanders."

### The Role of Lymphocytes in Autoimmune Diseases

The contribution of cellular immune phenomena to tissue damage in the so-called autoimmune diseases remains controversial. It has been suggested that autosensitized lymphocytes may play a role in the clinical manifestations of rheumatoid arthritis,<sup>328</sup> ulcerative colitis,<sup>350</sup> chronic liver disease,<sup>373</sup> Addison's disease,<sup>353</sup> and a number of neurologic diseases, including experimental allergic encephalomyelitis,<sup>277</sup> experimental allergic neuritis,<sup>277</sup> multiple sclerosis,<sup>290,360</sup> and the Guillain-Barré syndrome.<sup>338,360</sup>

### Antitumor Immunity

The concept of immunity against established tumors and the related concept of "immunologic surveillance" against emerging new clones of malignant cells<sup>407</sup> are based on two important hypotheses, namely, that tumor cells differ antigenically from normal cells and that host defense mechanisms are capable of recognizing and exploiting these differences. These hypotheses, first formulated with remarkable accuracy by Ehrlich in 1909,<sup>427</sup> have since been proved correct, both in animals and in man.<sup>410,421,422,425,427,433,440</sup>

Tumor specific transplantation antigens (TSTA or TSA), so named because their demonstration originally required transplantation techniques in syngeneic animal systems, are of two main types. Tumors induced by chemical carcinogens such as 3-methylcholanthrene<sup>410,434</sup> have tumor specific antigens that are distinct for each neoplasm. Even tumors induced in inbred strains and separate tumors induced in the same animal will all have different and readily distinguishable tumor antigens. In contrast, the tumor specific antigens of virus-induced tumors<sup>417,436</sup> are shared by all neoplasms caused by the same virus, even in different species. Such antigens are not present in the

virion or in normal cells before transformation. They represent, instead, structural alterations induced by the oncogenic virus within the host cells, probably on the basis of information contained within the viral genome.<sup>437</sup> Whether these changes represent newly synthesized antigens or uncovered subsurface antigens is not clear.<sup>406</sup>

When cells are infected with DNA oncogenic viruses, they may also produce other neoantigens associated with the nucleus or cytoplasm of the cell.<sup>403,437</sup> Known as T (transformation) antigens, they are, like TSA, identical on all tumors induced by a given virus. Their nature and function are unknown.

*Viral antigens* (Table 7-7) are rarely seen in DNA induced tumors but are regularly found in RNA induced tumors. Two types of viral antigens are recognized: (1) virus coat antigens and (2) antigens ordinarily confined to the viral core. Virus coat antigens are found on the cell surface, principally in areas of virus budding, whereas the cytoplasm contains both soluble coat antigens and virus core antigens. The latter include a number of viral proteins and enzymes, the best known of which is the RNA-dependent DNA polymerase.<sup>399</sup>

Tumor specific and structural viral antigens may be detected by a number of techniques which have been described elsewhere.<sup>410,437</sup>

Some antigenic materials produced by

**Table 7-7. Antigens of Virus-Induced Tumors**

tumors are released from neoplastic cells into the circulation and body fluids. Such materials include  $\alpha$ -fetoprotein, found in the majority of individuals with hepatomas,<sup>410,413</sup> and carcinoembryonic antigen (CEA), found in the circulation of patients suffering from colonic carcinoma and other gastrointestinal neoplasms.<sup>410,414</sup> A closely related or identical antigen has been found in the sera of patients suffering from non-intestinal neoplasms (eg, breast, lung, prostate) or non-neoplastic disorders such as renal disease and alcoholic liver disease.<sup>410a,430a</sup> Different fetal proteins have been identified in other types of tumors.<sup>414</sup> It is also possible that soluble tumor specific antigens are shed into the circulation and body fluids where they may have an adverse effect on antitumor immunity (page 331).

*Immunity against tumor specific antigens* has been demonstrated by a variety of techniques, in both animals and man. Initially, tumor specific immunity was demonstrated by immunizing syngeneic animals against a tumor and subsequently challenging them with viable tumor cells.<sup>425,440</sup> Later, *in vitro* tests were developed for the detection of humoral and cellular antitumor immunity (Table 7-8). The colony inhibition test ap-

pears to be a particularly sensitive tool.<sup>419,422</sup> In this test, target tumor cells are incubated with antiserum or normal serum in the presence of complement and are plated on Petri dishes. The growth of colonies in antiserum treated cultures is compared to that in control cultures. When lymphocytes are used instead of antisera, the test can be used to measure cellular antitumor immunity.

Immunity against a large number of human neoplasms has now been established.<sup>422,423</sup> Such tumors include melanoma,<sup>430,431</sup> neuroblastoma,<sup>419</sup> Wilms' tumor,<sup>411</sup> choriocarcinoma,<sup>402</sup> and carcinomas of the colon,<sup>423</sup> breast,<sup>401,423</sup> lung,<sup>423</sup> ovary,<sup>423</sup> and bladder,<sup>405</sup> as well as several malignancies of special interest to hematologists, such as leukemia,<sup>416,435</sup> Hodgkin's disease,<sup>432</sup> and Burkitt's lymphoma.<sup>404,426,427</sup>

At this point it is relevant to ask whether the demonstration of antitumor immunity *in vitro* is of any consequence to tumor growth *in vivo*. Evidence for the importance of an intact system of antitumor immunity *in vivo* comes from a number of clinical observations and parallel *in vitro* studies: (1) Circumstantial evidence is derived from the observation that the incidence of malignancy is inordinately high in patients suffering from a

Table 7-8. Tests for Antitumor Immunity<sup>410</sup>

Technique	Source of Tumor Antigens	Immune Reagents	
		Type	Source
Precipitin (Duchterlony radioimmunoassay)	Soluble antigens from serum and body fluids	Antibody	(a) Sera from cancer patients, usually after excision or recovery (or from mothers in vertically transmitted tumors)
Fluorescent staining			(b) Immunized animals eg as a source of anti-CEA
Colony inhibition Cytolytic (target cell destruction)	Tumor cells	Antibody or lymphocytes	Cancer patients (or mothers in vertically transmitted tumors)
Lymphocyte transformation Macrophage migration inhibition	Tumor cells or soluble antigens	Lymphocytes	Cancer patients

variety of immune deficiency syndromes (Chapter 44), and in those subjected to chronic immunosuppression.<sup>415</sup> (2) There appears to be some correlation between prognosis and the overall immune status of the patient, both in leukemia (page 1397) and in other tumors.<sup>428,441</sup> (3) The most compelling evidence for a close link between immunity and malignancy comes from observations relating specific antitumor immunity to the prognosis of the patient. In several human tumors, especially malignant melanoma and colonic carcinoma,<sup>430</sup> the presence of antitumor antibodies in the serum is clearly associated with early or localized tumors, whereas dissemination of the tumor with metastases is associated with a lack of detectable antibody. Somewhat different results have been obtained with studies of cell-mediated antitumor immunity,<sup>420,422,423,437</sup> since there appears to be some discrepancy between the performance of the patient's lymphocytes *in vivo* (as judged by tumor progression) and the assessment of their capabilities *in vitro*. For, contrary to earlier expectations, there is no substantial difference between the *in vitro* antitumor activity of lymphocytes obtained from individuals in remission and from those with rapidly advancing tumors.<sup>423,437</sup> Thus patients with growing tumors do not suffer from a major breakdown of cell-mediated antitumor immunity. Instead, the tumors appear to be protected from the cytotoxic effects of specifically sensitized lymphocytes by blocking factors recoverable from the sera of patients with growing tumors. This blocking activity has the same immunologic specificity as the patient's immune lymphocytes and preliminary data indicate that it contains noncytotoxic 7S antibodies against tumor specific antigens.<sup>420,423</sup> Thus the protection of tumors by blocking sera bears some resemblance to the phenomenon of immunologic enhancement described in experimental tumor systems and allograft rejection (page 327): the tumor is protected against the cytolytic activity of sensitized lymphocytes because the surface bound tumor specific antigens are pre-empted by blocking antibodies.

In other experiments, blockade appears to be due to the presence of antigen-antibody

complexes in the serum.<sup>438,439</sup> The blockade is abolished when these complexes are dissociated, and is restored when the two parts are combined. These complexes may be capable of blocking lymphocytes by attachment to specific antigen receptors, whereas free antibody is restricted to blocking antigenic sites on tumor cells.

The sera of individuals in remission do not contain this blocking activity; its appearance may precede clinically detectable evidence of relapse.<sup>437</sup> Indeed sera of patients in remission appear to be capable of unblocking the sera of animals and patients with growing tumors.<sup>438,423</sup> In animals unblocking sera are capable of inducing tumor regression *in vivo*.<sup>423,437</sup> The implication of this finding for human immunotherapy needs to be explored.

The mechanisms of tumor rejection by lymphocytes are thought to be similar to those described for allograft rejection (page 327).

Undoubtedly, protection against malignant growth is not confined to lymphocytes and antibodies with specificity for tumor specific antigens. It is likely, for instance, that interferon plays a role in the protection against virus-induced malignancies.<sup>302,323</sup> Indeed, since oncogenic viruses are also immunosuppressive<sup>415</sup> and may therefore aid their own establishment in transformed cell lines, interferon may play an important protective role, especially in the early stages of tumor induction. The role of macrophages in antitumor immunity also needs further exploration. Destruction of tumors by macrophages from sensitized mice has been demonstrated both *in vivo* and *in vitro*.<sup>285</sup> It is possible that macrophages become cytotoxic by virtue of their ability to concentrate cytophilic antitumor antibody, or because of their activation (page 322) by products of sensitized lymphocytes.

#### Tolerance<sup>400,412,429,430b,413</sup>

Immunologic tolerance is an induced state of specific nonreactivity toward a substance that is ordinarily immunogenic. This type of specific tolerance depends on the interaction

between antigen and immunologically competent cells and is characterized by the subsequent failure of these cells to participate in the immune response. Tolerance is restricted to the antigen eliciting its induction and thereby differs from the nonspecific unresponsiveness induced by radiation, antilymphocyte serum, or drugs in the absence of antigen.

Other types of antigen induced immunologic unresponsiveness are due to interference with peripheral immune mechanisms rather than to the central paralysis of immunocompetent cells. These include the competitive inhibition of immune responses by haptens,<sup>430b</sup> soluble antigens, and antigen-antibody complexes (see blocking factors in antitumor immunity, page 331), as well as the phenomenon of antigenic competition.<sup>263</sup>

Whether immunization with a given antigen results in immune competence or tolerance depends to some extent on host factors, but, more importantly, on the nature of the inciting antigenic stimulus.<sup>430b,443</sup> *Host factors* favoring tolerance induction include immunologic immaturity, eg, during fetal development, and temporary but generalized states of immunosuppression due to radiotherapy or drugs, which are thought to mimic developmental immaturity. If antigen is introduced under these conditions, specific immune tolerance may result while the remainder of the immunologic apparatus develops or recovers normally.

**ANTIGENIC FACTORS.** In order to be tolerogenic (as opposed to immunogenic) antigen must reach all cells capable of reacting with it.<sup>413</sup> Thus small (monomeric) antigens that readily reach extravascular sites are more effective than are polymeric or aggregated antigens.<sup>412</sup> In addition, macrophages are less capable of fixing monomeric antigen,<sup>443</sup> and their important role in the induction of immune responsiveness (page 314) is thereby pre-empted. Instead, monomeric antigens may interact directly with specific immune responsive cells; this interaction may result in their removal or it may prevent their subsequent interaction with immunogenic forms of that antigen.

Tolerance may also be induced with very large ("high zone tolerance") or very small ("low zone tolerance") doses of antigen. High zone tolerance<sup>430b,443</sup> may be due to an exhaustive differentiation of cells specifically interacting with this antigen or to the direct access of antigen to lymphocytes without the participation of macrophages. The direct access theory has also been invoked to explain low zone tolerance,<sup>412,430b</sup> since macrophages bind antigens less efficiently than cells carrying specific antigen receptors; this gives lymphocytes a competitive advantage at very low concentrations of antigen. It also follows that cells with high affinity receptors should be more susceptible to tolerance induction than cells with low affinity receptors.<sup>442</sup>

Tolerance is not permanent and recovery may occur spontaneously or following a number of therapeutic maneuvers. *Spontaneous recovery* is affected by the persistence of antigen, the type of antigen, and age.<sup>412</sup> Thymectomy interferes with the recovery of immunologic reactivity.<sup>443</sup> Recovery may be induced by immunization with cross-reactive antigens and radiotherapy,<sup>430b,443</sup> the latter especially in partially tolerant states.<sup>443</sup>

Under most circumstances both T and B cells are rendered unresponsive,<sup>443</sup> although unresponsiveness of either component alone would affect antibody production. However, thymus derived (T) cells become unresponsive more readily than B cells and remain so for longer periods of time.<sup>443</sup> Macrophage function remains normal during tolerance.

**RELEVANCE TO DISEASE.** It has been suggested that the pathogenesis of some autoimmune disorders is related to a loss of tolerance for autoantigens, such as thyroglobulin in immune thyroiditis.<sup>413</sup> In other diseases, for instance rheumatic fever, tolerance may be "broken" by the production of antistreptococcal antibodies that cross-react with heart muscle fiber glycoproteins.<sup>424</sup> In addition, the widespread use of highly immunosuppressive drugs in the treatment of hematologic malignancies (Chapter 55) may foster the development of undesirable tolerance to a variety of determinants such as those of infectious agents and other tumor specific antigens.

## Complement<sup>446,447,468,480</sup>

The complement system consists of a group of 11 distinct serum proteins that interact sequentially to mediate certain effects of the inflammatory response. During the course of this reaction sequence the complement system also interacts with at least three other plasma protein systems, namely, the clotting system, the fibrinolytic system, and the kinin generating system.

### Nomenclature<sup>449</sup>

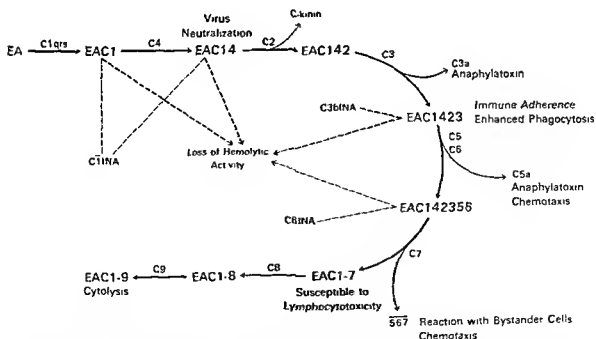

Most of our knowledge about the nature of the complement system has come from studies of sheep erythrocytes (E) treated with antibody (A) and complement (C). The various complement components interacting with the EA complex are indicated by arabic numerals, eg, C1, C3, etc. The first component, C1, consists of three subunits designated C1q, C1r, and C1s. Activated complement components in the fluid phase are indicated by a bar over the component number, eg,  $\bar{C}1$ . Activated components bound to cell surfaces are not so marked. Complement fragments

resulting from activation are suffixed sequentially with lower case letters, eg, C4a, C4b and the major hemolytically inactive fragments of each component receive the suffix "i", eg, C4i. Inactivators of specific complement components are indicated by the letters INA following the component in question, eg, C6INA.

Longstanding usage has led to the designation of the first four components in the reaction sequence as C1, C4, C2, and C3, in that order.<sup>448</sup> The remaining five components follow the more logical ascending numerical order.<sup>448</sup> The terms  $\beta 1E$ ,  $\beta 1C$ , and  $\beta 1F$  formerly designated the C4, C3, and C5 components, respectively.

### The Complement Cascade<sup>448,480</sup> (Fig. 7-18)

C1 is a complex molecule consisting of three proteins, C1q, C1r, and C1s, and calcium ions. The C1q subunit of C1 bears the combining site for the Fc portion of immunoglobulins and initiates the complement cascade by reacting with IgG or IgM antibodies that have combined with antigen or have been

aggregated by other means. The reaction requires either two IgG molecules that have reacted with antigen in critical proximity to each other, or two subunits ("monomers") of a single IgM molecule. Only IgG1, IgG2, and IgG3 antibodies are capable of activating complement, IgG4 is not (page 309). C1q then brings about the activation of C1r, which in turn converts C1s from a pro-esterase to an active esterase. This enzyme splits C4 into at least two portions, C4a and C4b, the larger of which, C4b, either becomes bound to the cell, forming EAC14, or remains in the fluid phase as the hemolytically inactive C4i. The smaller fragment (C4a, molecular weight 7,400) also appears free in the fluid phase. The interaction of C4 with C1 unmasks the capacity of the C1 enzyme to split its second natural substrate, C2, the major fragment (C2a) being bound to the cell surface in the presence of magnesium ions, thereby generating EAC142, a new enzymic activity, referred to as C3 convertase. This enzyme is very unstable and decays rapidly with the spontaneous release of the C2d fragment into the fluid phase.

Through the action of C3 convertase, C3 is split into a small fragment, C3a, and a larger fragment, C3b. The C3a fragment (anaphylatoxin) is released into the fluid phase. It causes a local wheal and flare reaction when injected intracutaneously in man, releases histamine from guinea pig mast cells in vitro, and causes the isolated guinea pig ileum to contract.<sup>455,465</sup> C3b is bound to form the cellular intermediate EAC1423 or remains free in the fluid phase as the inactive product C3i. The presence of C3b on the cell surface confers upon it the ability to participate in the phenomenon of "immune adherence"; this is a reaction in which C3b coated cells bind to specific receptor sites on platelets, polymorphonuclear leukocytes, and erythrocytes.<sup>462</sup> Binding of C3b coated cells to polymorphonuclear leukocytes is thought to enhance phagocytosis.

The C423 enzyme on EAC1423 cleaves C5 into C5a and C5b. The smaller C5a fragment is liberated into the fluid phase and has anaphylatoxin and chemotactic activity.<sup>458,491</sup>

The major fragment, C5b, is bound to the complex to form the EAC14235 intermediate which is quite unstable until the sequential binding of C6 and C7 has been completed.<sup>484</sup>

In the course of EAC1-7 formation, a factor that interacts with other bystander cells and is chemotactic for polymorphonuclear leukocytes is generated. This property is distinct from C5a and appears to be mediated by the trimolecular complex C567.<sup>492</sup>

The fixation of C8 to the EAC1-7 cell initiates membrane damage, but the rate of lysis is slow.<sup>493</sup> The addition of C9 markedly increases the rate of lysis. Cellular damage by human complement is associated with typical membrane changes, which on electron microscopic examination have the appearance of 10.3 nm holes.<sup>477</sup>

The biologic properties of complement are summarized in Table 7-9. Most complement components appear to be produced by macrophages with the possible exception of the intact C1 macromolecule which is either synthesized or assembled within intestinal tissue.<sup>480</sup>

**CONTROL MECHANISMS.**<sup>480</sup> Complement activity is limited by the presence of inhibitors and by the instability of some of its components, especially EAC142 and EAC14235. Inhibitors include C1INA, C3bINA, and C6INA.

**Table 7-9. Biologic Properties of Complement**

Complement Component	Biologic Activity
1 4	Virus neutralization
3b	Immune adherence Enhanced phagocytosis Arthus reaction
3a 5a	Anaphylatoxins Increased vascular permeability Arthus reaction
3a 5a 5 6 7	Chemotaxis of leukocytes Arthus reaction
1-9	Cell lysis Bactericidal reaction Transfusion reaction

### Alternate Pathways of Complement Activation<sup>169,480</sup>

Studies dealing with the activation of complement by zymosan, a polysaccharide extracted from yeast cell walls, lipopolysaccharide, and cobra venom factor (CoVF) have yielded incontrovertible evidence of an alternate pathway of complement activation that bypasses the activation of C1, C4, and C2.<sup>480</sup> In these alternate pathways the C3 activator system (see below) rather than C3 convertase (page 334) is responsible for the generation of C3b and C3a from C3, and the properdin system,<sup>472</sup> forgotten for over a decade, plays an important role.

*Properdin*<sup>470</sup> is a 5S  $\gamma_2$  glycoprotein of molecular weight  $180,000 \pm 12,000$  and seems to consist of four noncovalently bound subunits of 45,000 daltons each. It is an early reactant in the sequence leading to complement activation by the alternate pathway and requires at least three other constituents previously designated factors A, B, and D. *Factor A*, a hydrazine-sensitive euglobulin with

a molecular weight of 180,000, is in fact C3.<sup>469</sup> Factor B is a glycine rich, heat labile  $\beta$ -glycoprotein (GBG) which is identical to the C3 proactivator (C3PA) identified by others.<sup>469</sup> The third constituent is C3PA convertase (also called C3Pase, GBGase, or *factor D*), a euglobulin of 30,000 to 40,000 daltons; this factor converts inactive C3PA to the C3-cleaving enzyme, C3 activator (C3A).<sup>469</sup>

**PROPERDIN REACTION SEQUENCE.** Properdin is activated by inulin polysaccharides and other substances and reacts with C3 in such a way that it acquires C3Pase-activating capacity. This enzyme, in turn, utilizes C3PA as substrate, and the major product, C3A, then cleaves C3 to yield the C3a anaphylatoxin and C3b. C3b then initiates a positive feedback activation of C3Pase which is independent of properdin and activating substances such as inulin. This amplification loop is illustrated in the right hand panel of Figure 7-19. The C3b inactivator C3bINA exerts a controlling or damping influence on this feedback effect.<sup>477a</sup> When fixed on a cell sur-

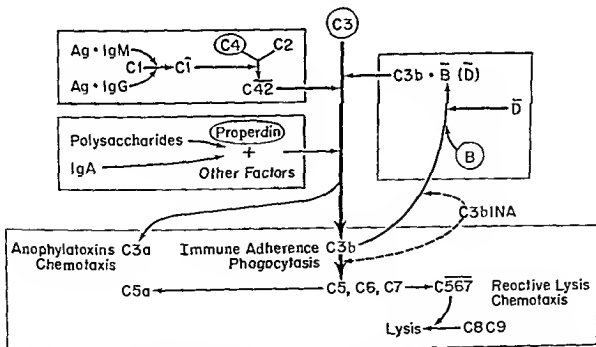

Fig 7-19. Interrelationships between the classic and alternate pathways of complement activation and the biologic activities associated with complement components 3 to 9. B = Factor B = C3PA, D = C3PA convertase (From Fearon et al.<sup>455a</sup> courtesy of the authors and *Advances in Nephrology*)

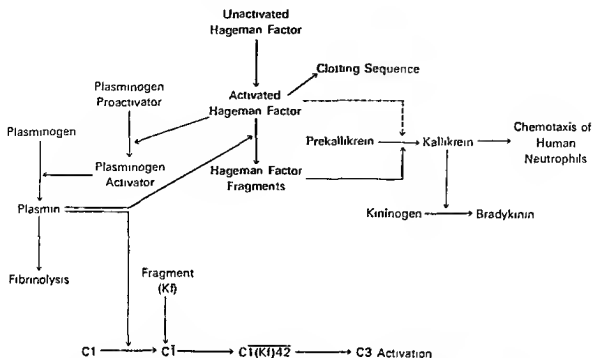

Fig 7-20 Interrelations between the coagulation, kinin generating, fibrinolytic and complement systems (From Ruddy et al.<sup>460</sup> courtesy of the authors and the New England Journal of Medicine)

face C3b can also engage the later C components, as discussed in the classic system (above). In addition, C3b can mediate the destruction of terminal C components in the fluid phase, and C3b itself can be inactivated by another protein called KAF.<sup>469</sup>

Alternate pathways are also activated by bacterial and fungal cell wall lipopolysaccharides, such as endotoxins,<sup>469,480</sup> and by cobra venom<sup>460,469,480</sup> and immunoglobulins.<sup>469</sup> Cobra venom factor (CoVF) forms a reversible complex with C3PA which has but feeble cleaving activity. C3PA convertase stabilizes this complex and enhances C3 cleaving activity. Another substance, *factor E*, is required for the enhancement of red cell lysis by this complex containing C3PA, CoF, and C3PA convertase. Immune activation of the alternate pathway ("C3 shunt") is mediated by sites found either on the Fc piece or on the F(ab)<sub>2</sub> fragment (page 306). Thus, aggregated F(ab)<sub>2</sub> fragments obtained from rabbit and guinea pig IgG as well as human IgA and IgE contain a site (near the hinge region) that is capable of activating complement via properdin and the alternate path-

way.<sup>490,469,482,483</sup> Reports concerning the ability of human IgG to activate the alternate pathway are conflicting.<sup>460,469</sup> Thus, immune activation via the alternate pathway provides a mechanism whereby IgA and IgE may activate complement and allows for the expression of antigenic specificity.<sup>480</sup>

#### Interaction of the Complement Sequence with Other Plasma Systems

The intricate entanglements of the clotting-fibrinolytic system, the complement sequence, and the kinin generating systems are illustrated in Figure 7-20.<sup>480</sup> (1) Activated factor XII (Chapter 10) initiates the clotting cascade and also activates the fibrinolytic system by the conversion of plasminogen to plasmin (Chapter 10). (2) Plasmin in turn digests activated factor XII with the production of active fragments which lead to kallikrein activation.<sup>463</sup> A limited degree of kallikrein activation is also mediated by activated factor XII. Kallikrein is directly leukotactic for human leukocytes and cleaves kininogen to yield vasoactive bradykinin.<sup>464</sup>

(3) The broad proteolytic activity of plasmin also includes the cleavage of C3 to yield anaphylatoxin (not shown)<sup>488</sup> and the activation of C1 to C1<sup>i</sup>.<sup>473</sup> In addition, the proteolysis of activated factor XII by plasmin leads to the activation of the kinin generating system, which in turn is associated with the appearance of a serum fragment, Kf,<sup>459</sup> that alters the function of C1 in such a way that its interaction with C4 and C2 leads to a more efficient generation of C3 convertase.<sup>480</sup>

A compendium of inherited and acquired defects in complement function is found in Table 7-10.

## Methods of Examination

### Morphologic Examination

#### Biopsy of Lymph Nodes

Biopsy of enlarged lymph nodes often is an important diagnostic step in differentiating the various types of primary and secondary lymph node diseases as discussed in Chapter 40. In addition, however, a lymph node biopsy specimen may be useful in the assessment of immunologic function in patients suspected of having immune deficiency dis-

eases (Chapter 44). In such instances biopsy should be done approximately one week after local antigenic stimulation, for instance, by the injection of diphtheria or tetanus toxoid into skin areas drained by the node to be excised. Lymph nodes should be examined to assess the thymus dependent paracortical areas and the lymphoid follicles and germinal centers as well as the number of plasma cells in the medullary cords.<sup>515</sup> Lymph node biopsy is not necessary in the diagnosis of severe combined immune deficiency and may be detrimental since lymph nodes are hard to find and infection may ensue.<sup>513</sup>

*Lymph node puncture*<sup>521</sup> is also helpful in the differential diagnosis of various lymph node disorders and metastases of malignant tumors. In this procedure the overlying skin is cleansed and a 20-gauge needle, attached to a dry syringe, is inserted into the node, which is firmly held between the thumb and index finger. The tissue is aspirated rapidly and the needle is withdrawn. Smears are made on a dry slide and stained with Wright's stain.

#### Splenic Biopsy

The value and technique of *splenic biopsy* are discussed in Chapter 8.

**Table 7-10. Abnormalities of Complement System**

#### *Inherited abnormalities*

##### *Classic complement pathway*

- 1 C1—inhibitor deficiency—hereditary angioneurotic edema<sup>478</sup>
- 2 Deficiency of C1q associated with immune deficiency syndromes<sup>455, 456</sup>
- \*3 C1r deficiency<sup>454</sup>
- \*4 C2 deficiency<sup>449, 479</sup>
- 5 Familial C5 dysfunction with deficient opsonization<sup>467</sup>

##### *Alternate pathway*

- 1 Abnormality of alternate pathway with recurrent infection<sup>446, 476</sup>

#### *Acquired abnormalities*

- 1 Complement activation by abnormal immunoglobulins
  - (a) Monoclonal gammopathy<sup>452</sup>
  - (b) Mixed cryoglobulinemia<sup>475</sup>
  - (c) Lymphosarcoma with IgM monomers<sup>482</sup>
- 2 Hypocomplementemic chronic glomerulonephritis<sup>437, 446, 459, 493</sup>
- 3 Decreased synthesis in liver disease<sup>471</sup>

\* High incidence of autoimmune diseases

## NORMAL HUMAN SERUM

Fig 7-21 Normal electrophoretic pattern of serum proteins. Cellulose polyacetate, Gelman Sepharose III system (Courtesy of M. McMorran and F. Paraskevas, Manitoba Institute of Cell Biology)

## Rectal Biopsy

Rectal tissue is readily accessible for biopsy and may be examined for plasma cells, either by ordinary histologic procedures or

by immunofluorescence techniques. Absence of plasma cells from the lamina propria reflects a defect of the secretory immunoglobulin system.<sup>505</sup>

*Lymphangiography* is the radiologic study

of radiopaque, contrast-filled lymph nodes and vessels that cannot be examined by simple clinical means, such as those of iliac and para-aortic chains. A radiopaque dye is injected into the lymphatic channels of both feet and is carried into the above-mentioned nodes. The clinical application of this technique, its usefulness, limitations, and dangers are discussed in Chapter 40.

### Functional Assessment of Humoral Immunity

For routine clinical purposes the following procedures are recommended: (1) a preliminary assessment of serum proteins by electrophoresis or immunoelectrophoresis, (2) quantitative measurement of various immunoglobulins, eg, IgG, IgA, IgM, etc.; and (3) assessment of the capacity to produce specific antibodies.

### Immunoglobulin Concentrations

#### *Protein Electrophoresis*

Proteins migrate in an electric field except at the pH of their isoelectric point. The rate of migration depends on the net charge of the protein and hence on the pH and ionic strength of the solution, and, to a lesser extent, on the size and shape of the molecule. Electrophoresis may be carried out in solution or by using porous inert media such as starch, silica gel, or, most often, moistened filter paper. Figure 7-21 shows the electrophoretic pattern obtained with normal human serum. The peaks represent groups of proteins separated on the basis of their mobility: albumin,  $\alpha_1$ - and  $\alpha_2$ -globulin,  $\beta$ -globulin, and  $\gamma$ -globulin. Antibodies occur predominantly in the  $\gamma$ - and  $\beta$ -globulin peaks. It is possible to assess the proportion of different components by measuring the fraction of the total area attributable to each component.

#### *Immunoelectrophoresis*

A more satisfactory separation of serum proteins is obtained by *immunoelectrophoresis*, a technique that makes possible the differen-

tiation of proteins on the basis of electrophoretic and immunologic properties. Separation of individual proteins is achieved by electrophoresis in agar gel. Later, antisera reacting with one or all plasma proteins are added to a long trough in the agar gel, beside the separated protein fractions. Within a few hours precipitin lines form at points of contact between the diffused proteins and their specific antisera in the trough. With this technique a large number of serum proteins have been identified by the characteristic position, shape, and intensity of their precipitin lines (Fig. 7-22).

### Quantitative Assessment of Immunoglobulins

The concentration of specific immunoglobulins is best determined by a variety of techniques that depend on the precipitation of proteins by specific antisera. They include single radial diffusion and double diffusion in agar gel,<sup>508, 518</sup> immunoelectro-diffusion,<sup>511</sup> and radioimmunoassay.<sup>522</sup> In all these techniques the immunoglobulin concentration of the test serum is compared with a standard solution of defined concentration.

Levels of IgG subclasses may also be measured by the single radial diffusion assay.<sup>518</sup> When dealing with extremely low concentrations of immunoglobulins, inhibition of hemagglutination tests has been found useful.<sup>523</sup> Secretory immunoglobulins may be measured following concentration of secretions obtained from parotid saliva, the gastrointestinal tract, and elsewhere.

Normal immunoglobulin levels for various ages are found in Appendix A (Table A-24).

### Antibody Formation

Titers of "naturally occurring" antibodies such as A and B isohemagglutinins, heteroagglutinins (eg, against sheep red cells) and antibodies against ubiquitous bacteria or their products (eg, antistreptolysins) are useful in screening for humoral immune deficiencies. Most children have been immunized against diphtheria, tetanus, and pertussis. Determination of antibody titers against these speci-

Fig 7-22 Immunoelectrophoretic pattern of normal human serum, using horse antiserum (Courtesy of Hyland Division Travenol Laboratories Inc)

ficties, preferably following a recent booster, is of great value. Other harmless antigens, which may be useful for active immunization, include the polysaccharides derived from pneumococci, *H. influenza* and *N. meningitidis* antigens,<sup>513,516</sup> the Vi antigen, and flagellin.<sup>520</sup>

Live vaccines such as vaccinia, polio, measles, rubella, BCG, and tularemia should *never* be used in patients suspected of having an immune deficiency.

Recommended vaccines, dosages, and intervals between immunizations are listed in Table 7-11.<sup>513</sup> Preferred methods for determination of antibody levels have been published.<sup>513</sup>

#### Functional Assessment of Cellular Immunity

Tests commonly employed for assessing cell-mediated immunity include (1) skin tests

for delayed hypersensitivity, (2) *in vitro* stimulation of lymphocytes to divide and form blast cells, and (3) the assessment of functions mediated by soluble lymphocyte products.

#### Skin Tests

Skin tests must be done with a battery of antigens, since universal sensitivity to any single agent does not exist. In varying dilutions, 0.1 ml of the following antigens is injected intradermally<sup>513</sup>; skin tests are read 48 hours later and the degree of erythema and induration is recorded in millimeters: (1) candida 1:10 for infants, 1:100 or 1:1000 for older children and adults; (2) tuberculin 1:10,000, if negative repeat at 1:1000; (3) Trichophyton, as for candida; (4) streptokinase-streptodornase, at a concentration of 5 units per 0.1 ml, if negative repeat at 40 units per 0.1 ml; (5) mumps antigen in stand-

ard dilution. Additional antigens include coccioidin and other agents having a high rate of reactivity in specific geographic regions.

*Active sensitization* may be carried out with contact allergens such as 2,4-dinitrochlorobenzene (DNCB).<sup>503</sup> This agent is highly irritating, especially in young children, and unpleasant burn reactions may occur. It should *never* be injected intradermally! DNCB is dissolved in acetone to form a stock solution of 2000  $\mu\text{g}$  per 0.1 ml. Sensitization is carried out with doses of 1000 to 2000  $\mu\text{g}$  applied to the volar surface of the forearm. To prevent spreading over a large area, a stainless steel or plastic ring measuring 2 cm in diameter is pressed to the volar aspect of the forearm which is held in the horizontal position. The sensitizing dose is put into the ring. After the solution dries the area is covered for 24 hours. The site is examined at 14 days for a spontaneous flare, which denotes sensitization to remaining antigen. In the absence of a spontaneous flare a challenge dose of 50 to 100  $\mu\text{g}$  per 0.1 ml is applied and the reaction is read at 48 hours. Induration denotes a positive response, erythema alone does not. Patients with unusually strong reactions may also show vesiculation and ulceration in addition to induration.

Keyhole limpet hemocyanin also produces cellular immunity, but is not recommended for general use.<sup>513</sup>

### Lymphocyte Transformation

The small lymphocyte can be activated *in vitro* and *in vivo* to alter its structure and to express latent functions.<sup>1,13,24,354</sup> The process is known as "lymphocyte transformation" and must not be confused with that occurring in virus-induced neoplasia.

*In vitro* transformation may be induced by a variety of agents,<sup>24,354</sup> some of which stimulate most cells, whereas others stimulate only a select few. The former are exemplified by phytohemagglutinin (PHA), pokeweed mitogen (PWM), concanavalin A (ConA); and antilymphocyte serum, the latter by specific antigens.

### Biochemical Events in Transformation

(1) The first step in lymphocyte activation is thought to be the interaction of mitogens with a variety of specific membrane receptors.<sup>506,507</sup> (2) In PHA-stimulated cells this step is followed almost immediately by a

**Table 7-11. Recommended Immunization Procedures for Evaluation of Antibody Production**

Vaccine	Dose	Number of Doses	Interval between Doses	Time of Antibody Determination (in weeks after last dose)
OPT	0.5 ml IM	3	1 week	2
Polio (killed)	1.0 ml IM	3	2 weeks	2
Pneumococcal polysaccharide	0.1 mg IM	3	1 week	2
H influenza polysaccharide	0.05 mg SC	1	—	2
N meningitidis polysaccharide	0.05 mg SC	1	—	2
Vi antigen (E Coli)	0.1 mg SC	1	—	2
Flagellin	5 $\mu\text{g}$ SC	1	—	2

IM, intramuscularly, SC, subcutaneously

greatly increased turnover (up to 21-fold in 30 minutes) of membrane phosphatidyl inositol,<sup>509</sup> and is followed in the next 24 hours by an increased accumulation of all phospholipids.<sup>510</sup> (3) Within the first hour there is increased acetylation of histones (the basic nucleoproteins complexed with DNA), which appears to precede the increase in nuclear RNA synthesis and may indicate changes in the fine structure of chromatin and the ability of DNA to serve as a template for RNA synthesis.<sup>519</sup> (4) Increased synthesis of RNA, predominantly polydisperse RNA, occurs within 30 minutes to two hours,<sup>504,507</sup> and is preceded or followed immediately by increased protein synthesis<sup>519</sup> which includes new ribosomal proteins. (5) Morphologic changes, enlargement of the cell and reorganization of nuclei and nucleoli (described on page 287) begin within 24 hours, followed by increased endocytosis and redistribution of acid hydrolases within lysosomes.<sup>502</sup> (6) At 24 to 36 hours there is a gradual increase in the incorporation of <sup>3</sup>H-thymidine (<sup>3</sup>HTdR)<sup>285,507</sup>; for specific antigens the onset of <sup>3</sup>HTdR incorporation is delayed for six to 12 hours.

The S-phase (DNA synthetic phase) lasts for six to 10 hours and is followed by the G<sub>2</sub> phase, a premitotic phase, which lasts for two to four hours, and is accompanied by the synthesis of RNA and protein. The cell then undergoes mitosis.

### Laboratory Studies

**LYMPHOCYTE STIMULATION.** Lymphocyte stimulation may be evaluated in terms of morphologic changes or by the incorporation of <sup>3</sup>HTdR, measured either by radioautography or by direct counting of radioactivity. For clinical purposes the last is the most convenient and useful test, but it must be noted that morphologic changes do not parallel thymidine uptake in all situations.<sup>512</sup> Lymphocyte cultures are generally set up at concentrations of 1 to 3 × 10<sup>6</sup> cells per tube and contain appropriate concentrations of stimulants. The response in stimulated cultures is then compared to that of unstimu-

lated cultures. It is always essential to determine the phytohemagglutinin response of at least two normal donors simultaneously, in order to guard against nonspecific variables. The same applies to other mitogens.

The capacity to respond to PHA, ConA, and antigen *in vitro* appears to be a function of T lymphocytes,<sup>506</sup> and under most circumstances lymphocyte transformation appears to correlate well with reactions of cellular immunity *in vivo*.<sup>285,354</sup> However, discrepancies between the proliferative response to antigen *in vitro* and the ability to develop delayed hypersensitivity reactions and produce MIF have been noted, especially in patients suffering from chronic mucocutaneous candidiasis.<sup>285</sup>

In contrast to PHA and ConA, PWM appears to stimulate B cells as well as T cells.<sup>506</sup>

**MIGRATION INHIBITION FACTOR.** The interaction of sensitized T cells with antigen releases a number of biologically active materials (page 321). Release of MIF by such cells appears to be an excellent *in vitro* correlate of cell-mediated immunity *in vivo*.<sup>297</sup> The technique preferred at present involves culturing blood lymphocytes in the presence of antigen for 72 hours and adding the cell-free, concentrated supernatant to chambers containing guinea pig macrophages<sup>297</sup> (see Fig. 7-17).

**MIXED LEUKOCYTE CULTURES.**<sup>500,501</sup> When lymphocytes from unrelated individuals are mixed and allowed to grow *in vitro*, transformation occurs and apparently reflects a primary immune response *in vitro*. In this system lymphocytes function not only as mediators of immunity but also as carriers of antigens. Standard techniques for mixed leukocyte cultures have been published.<sup>500,501</sup> In most instances one cell population is rendered incapable of proliferation and serves as antigen whereas the other population furnishes the proliferating cells (one-way test).<sup>500</sup>

Apparently the capacity to respond to allogeneic cells is a property of T cells.<sup>506</sup> In several patients suffering from immune deficiency syndromes responses were seen in this

test, although the response to PHA was impaired.<sup>506</sup>

Tests of lymphocyte cytotoxicity against allogeneic cells or syngeneic tumor cells have been described previously (page 325).

## **The Reticuloendothelial (Mononuclear Phagocyte) System (RES, MPS)**

### **History**

The term "reticuloendothelial system" was first used by Aschoff<sup>1</sup> to designate those cells, widely scattered throughout the body, that

take up acid vital dyes with great avidity. It had been shown previously that the free and fixed large mononuclear cells of Metchnikoff ("macrophages" as opposed to the blood leukocytes or "microphages") in the omentum, liver, spleen, and other tissues had great affinity for these dyes. Later it was demonstrated that the electronegative charge of the dye, the degree of dispersion of dye colloid, and the blood supply to the tissues greatly influenced the intensity of tissue staining.<sup>8,12</sup> Subsequently, India ink, iron, and other metal particles were injected into animals and the patterns of tissue uptake were recorded. It became apparent that, under appropriate conditions of injection and especially after local tissue damage, dye or particle uptake occurred in a wide variety of tissues including reticular cells of the spleen, bone marrow and liver, renal tubular cells, capillary endothelium of the adrenal cortex and hypophysis, branched cells in the thyroid and parathyroid glands, myocytes in the heart, and glial cells in the central nervous system.<sup>8</sup> Furthermore, after repeated injections of dye or particulate material an even greater variety of cells participated in such storage. For example, particles of carmine or trypan blue dye first appeared in the epithelium of the convoluted tubules in the kidney. As injections continued, particles were found in adrenal cortex and hepatic cells (both Kupffer cells and hepatocytes) which swelled and became

stuffed with dye, and in some instances (eg, liver) were transformed into giant cells. The number of storing cells also increased as a result of local cell division and recruitment of new cells. After many injections, fine dye particles appeared even in fibrocytes and in the general vascular endothelium. In short, most body cells may ultimately become phagocytic under appropriate circumstances.

Aschoff divided the various cells that ingested injected dyes into four groups: Groups I and II consisted of endothelial cells of the blood and lymphatic vessels and the fibroblasts, all of which exhibited relatively weak staining; these cells were not included in the designation "reticuloendothelial system." Group III consisted of the reticulum cells of the spleen and lymph nodes. Group IV included the cells lining the sinusoids of the liver, bone marrow and lymph sinuses, similar cells in the adrenal and pituitary glands, and the free histiocytes in the splenic sinuses and other organs. Groups III and IV were thought to constitute a single functional cell system. It was because these cells seemed to be involved in reticulum formation or lined blood or lymph sinuses that the term "reticuloendothelial system" (RES) was coined. This functional unit, however, is not a distinct, cytologically identifiable one. A number of the cells of the RES may be identified in tissue sections by their staining reactions with metal salts ("metallophil" cells), but other undifferentiated, primitive reticular cells cannot be recognized in this way.<sup>12</sup>

### Definition of the RES

Because attempts to define the "RES" have not provided an improved definition<sup>6</sup> since Aschoff's studies<sup>13</sup> we will use the following working definition: the RES consists of the reticulum cells of the spleen and lymph nodes, the cells lining the sinusoids of the liver, bone marrow and lymph sinuses, as well as similar cells in the adrenal and pituitary glands and the free histiocytes in the spleen and other organs that avidly ingest injected dyes. As discussed in Chapter 6, because these cell types are now considered to

be derived from the blood monocytes, which in turn are the products of precursors in the bone marrow, they are increasingly being referred to as cells of the mononuclear phagocyte system (MPS) rather than of the RES. However, since the older literature refers to the RES it will often be necessary to use that designation.

### Size of the RES or MPS

Because the component cells are so diffusely distributed, the size of the RES is unknown. Nevertheless, estimates of the RE cell component of three of the major RE organs (the spleen, liver, and bone marrow) in the rat yielded approximately equal values for each of the organs, ie, about one billion RE cells.<sup>9,10</sup> From similar studies of organ weight and DNA content, the normal human spleen was estimated to contain 140 billion cells.<sup>9</sup> If it is assumed that about half of the total cells present in the spleen are RE cells (as in the rat) and that the liver and bone marrow contain an equal number of RE cells, the RES of man consists of at least 200 billion cells and constitutes a diffusely distributed organ of considerable size.

### Functions of the RES or MPS

In the spleen and lymph nodes the cells of the RES lie in close structural proximity to immunologically reactive cells, whereas in the liver and bone marrow these cells are in close contact with hepatocytes and hematopoietic cells, respectively. These associations suggest somewhat different and perhaps specialized functions of the RE cells according to their location. Nevertheless, the common denominator of the system as a whole appears to be the engulfing of particulate material and effete or damaged cells. The end result of such ingestion may vary from rapid killing and digestion of bacteria or red cells to indefinite storage of particles such as silica, carbon, and thorium dioxide. The clearing function of the system is thus fundamentally related to body defense.

### Clearing Capacity

The clearing capacity of the RES or MPS was quantitated by injecting increasing doses of carbon particles, saccharated iron oxide, colloidal gold or silver, thorium dioxide, or aggregates of serum protein into animals.<sup>3,4</sup> It was demonstrated that: (1) with increasing doses, the rate of particle clearance asymptotically approaches a maximal clearance rate; (2) in a given species the maximal clearance rates of different colloids are not the same; and (3) the maximal clearance (expressed as mg/100 g body weight) for a given colloid (eg, carbon) differs from species to species.<sup>3,4</sup> This variation in clearing capacity appeared to be a function of the weight of the spleen and liver since the clearance per 100 g of liver plus spleen was approximately the same in the several species studied.<sup>3</sup> It was also noted that maximal clearing capacity decreased as the animals grew older.

In rodents the clearance of injected colloids from the blood was best described by a single exponential function. At doses lower than the maximal clearance capacity of the system, about 85% of the colloid was found in the liver and 5% in the spleen. As the dose of injected colloid was increased, clearance by the spleen increased to about 20% of the injected dose.<sup>2</sup> The predominant clearance by the liver was thought to reflect differences in blood flow to the two organs and, in fact, the clearance rate of small doses of dye or other colloids is used to measure liver blood flow.<sup>2</sup> Since metal and dye particles are not metabolized and remain in the RES almost indefinitely, study of the RES clearing function in man became possible only when it was demonstrated<sup>7</sup> that, after measuring the clearance rate of aggregated serum albumin at several intermediate doses, the maximal clearing capacity could be calculated by using the analytic method of Michaelis-Menten.<sup>7</sup> The maximal rate of phagocytosis of aggregated albumin was found to be 1.07 mg/kg/min in man.<sup>7</sup>

The site of particle clearance by the RES is influenced by blood flow, local tissue damage, presence of opsonins, the nature of the

particles, and probably other factors. Thus, in man, the spleen has a special ability to clear mildly damaged erythrocytes from the circulation, whereas more severely damaged red cells are removed mainly by the liver.<sup>11</sup> Other sites are stimulated to activity under other conditions. For example, the RE activity of the bone marrow was found to be increased after the induction of marrow hypoplasia in rats.<sup>10</sup>

### Blockade of the RES

The clearing function of the RES can be blocked to a variable extent by the injection of particle suspensions (eg, carbon, saccharated iron oxide, thorotrast). That RES blockade is fairly specific was shown by the observation that clearance of a given particle is decreased more by prior injection of a blocking dose of that same particle than by injection of a different one.<sup>14</sup> The mechanism of this blockade specificity is unknown but the blockade may reflect saturation of a specific population of phagocytic cells or depletion of serum factors (opsonins) needed to facilitate phagocytosis. Morphologic examination after the simultaneous injection of a dye and a metal colloid demonstrated that some RE cells contained only dye while others contained only metal particles, thus supporting the concept that there are populations of phagocytic cells with a special affinity for different types of particles.<sup>18</sup> However, still other studies using chronic phosphate in rats suggest that RES blockade is not the result of general depression of RE cell function, saturation of particle specific cell clones, or depletion of serum opsonins. Rather, it was postulated that RES blockade occurs when large numbers of particles saturate the binding sites of macrophage membranes.<sup>5</sup>

The duration of RES blockade by nontoxic particulate matter such as carbon particles was found to be transient (less than 24 to 48 hours in rats) and recovery was associated with enlargement of the liver and spleen.<sup>3</sup> From this it was concluded that new cell formation, either locally or from recruited blood monocytes, was a major factor in re-

covery from blockade,<sup>3</sup> and it was demonstrated that cortisone or nitrogen mustard delayed recovery, presumably by depressing cell proliferation.<sup>4</sup> The duration of blockade varied with the dose given and with the type of particle; also blockade produced by readily metabolizable particles, such as aggregated albumin, lasted only three to four hours while the effects of gelatin and colloidal gold were more prolonged.<sup>18</sup> Nevertheless, recovery after blockade with nonmetabolizable particles does occur. Such materials become enclosed in intracellular vacuoles.<sup>19</sup>

### *Function of the RES in Body Defense*

Transient depression of RES phagocytic activity followed the intravenous injection of endotoxin or killed *Salmonella typhosa*.<sup>15,20</sup> This was succeeded by an increase in the weight of the liver and spleen and thereafter the phagocytic capacity was found to return to and exceed the normal range, just as after carbon injection.<sup>4</sup> However, the injection of virulent organisms into mice (*S. Danysz*, *S. typhimurium*, and several strains of tubercle bacilli) produced similar changes initially, but then damage to the RES supervened, small abscesses appeared, and most of the mice died.<sup>4</sup> The size of the infective dose and the virulence of the organisms appeared to be the main determinants of the outcome. Not all bacteria alter RES (MPS) activity since dead staphylococci when injected had no effect on the system.<sup>4</sup> Significantly, artificial stimulation of the system by serial injections of aggregated serum proteins markedly enhanced the ability of rats to resist experimental infection with *S. typhimurium* (95% survival after 17 days in the treated group as compared to almost 100% mortality in the controls),<sup>4</sup> and RES blockade increased the lethality of certain induced infections<sup>4</sup> or rendered naturally resistant animal strains susceptible. Pneumococcal pneumonia, typhoid fever, or tularemia in man enhanced the phagocytic capacity of the RES as measured by aggregated albumin clearance.<sup>16</sup> The persistence of increased RES function for several days after cessation of bacteremia was interpreted as indicating a nonspecific, de-

bris-clearing function.<sup>16</sup> In contrast, the viral infections, sandfly fever, and dengue decreased RES function as measured by aggregated albumin clearance,<sup>16,17</sup> possibly by interfering with energy sources in the phagocytes.<sup>4</sup>

The inability to kill certain organisms may explain some chronic diseases such as tuberculosis, syphilis, and chronic granulomatous disease, and inability to completely metabolize a variety of cellular components appears to explain Gaucher's disease and other storage disorders (see Chapter 42).

## **The Spleen**

The spleen intrigued Galen in the third century and many physicians and investigators since then,<sup>113,114</sup> but only in very recent times has it begun to be less of an organ of mystery, the "mysterium plenum organum" of Galen. That the spleen is closely related to the hematopoietic system is evident since it becomes enlarged in association with a variety of blood diseases and some of these diseases are ameliorated when it is removed. Furthermore, striking changes are found in the blood after splenectomy. However, what functional role the spleen normally plays and how these functions are carried out have only recently begun to be understood. Before discussing these, the unique structure of this organ needs to be understood.

### **Structure<sup>29,31</sup>**

In adult man the spleen is enclosed in a connective tissue capsule that is several millimeters thick. The capsule contains few muscle cells, and thus the human spleen is not capable of the marked contractions seen in the spleen of the cat or dog. From the internal surface of the capsule an extensive, branching network of trabeculae divides the organ into communicating compartments. This network is well seen in spleens digested to show the gross trabecular structure.<sup>31</sup> The appearance is not unlike that of a sponge, with the spaces containing the parenchymal or pulp tissue. The parenchyma is composed

of two types of tissue, the *white pulp* and the *red pulp*. These will be described below.

The splenic capsule is deeply indented on the medial surface where the nerves, lymphatics, and blood vessels enter. The lymphatics are restricted to the capsule and *trabeculae* and are essentially absent from the parenchyma. The nerves are those of the sympathetic nervous system and are associated with the blood vessels well out into the pulp, perhaps as far as the terminal capillaries. The splenic artery branches at the hilum into multiple *trabecular arteries* that in turn give off branches that leave the trabeculae

and enter the parenchyma (Fig. 8-1). The branches of the trabecular arteries, called *central arteries* because of their central position in a sheath of white pulp, are medium-sized, muscular vessels that can markedly vary blood flow by their contraction or relaxation.<sup>26</sup> From them and their secondary branches even smaller branches are given off in a radial fashion and these enter the white pulp where, after further branching and arborization, they terminate in the marginal sinus or enter the marginal zone of the red pulp (Fig. 8-2).<sup>30</sup> After distributing multiple branches to or through the white pulp the

### WHITE PULP

### RED PULP

Fig. 8-1. Diagram of the splenic structure and circulation. The components of the white pulp are listed on the left, those of the red pulp on the right.

Fig. 8-2 A Capillaries (C) in the rat spleen are shown traversing a lymphatic node (LN) of the white pulp and entering the marginal sinus (MS). The marginal zone (MZ) and the red pulp (RP) are seen at the right (X 180). B A white pulp capillary (C) is shown leaving the area of the lymphatic node (LN) and traversing the marginal zone (MZ) to enter the red pulp (RP) (X 190). C A capillary (C) of red pulp origin opens into the marginal sinus (MS). The arrow indicates a marginal sinus pore (X 740). (From Snook,<sup>28</sup> courtesy of the author and Wistar Institute of Anatomy and Biology.)

attenuated main central artery divides into several branches that run on into the red pulp. These branches are the *penicilli* (vessels about 25  $\mu$ m in diameter which contain in their walls smooth muscle, basement membrane, and adventitial cells [Fig. 8-1]). They may terminate or continue on to become arterial capillaries, some of which may be sheathed by closely packed phagocytic cells and reticular fibers.<sup>23</sup> Most of these capillaries appear to terminate in the cordal tissue of the red pulp or in the marginal zone. Only a rare vessel terminates in close proximity to or directly connects with a sinus.<sup>25,31</sup>

The supporting structure of the parenchyma consists of a diffuse network of large, branched or stellate reticular cells and the reticular fibers that they produce. On electron microscopy these fibers can be seen within, as well as outside, the reticular cells, and in the latter location they are often partially ensheathed by reticular cell cytoplasm. The reticulum is morphologically and immunologically related to basement membrane and cement substance.<sup>31</sup> The arrangement of reticular cells and fibers is somewhat different in

the white pulp than in the red pulp and the cells interspersed within the pulps differ also.

In the *white pulp* the reticular cells and fibers are circumferentially and loosely arranged around the central artery. In this meshwork, predominantly small lymphocytes plus variable numbers of plasma cells, macrophages, and a few other cells lie free (*lymphatic sheaths*); red cells are few in number. Adjacent lymph follicles, eccentrically located in relation to the central artery, comprise a major portion of the white pulp (Fig. 8-1).

The *red pulp* consists almost entirely of thin-walled *splenic sinuses* and the *splenic cords* which lie between them. The sinuses are vascular channels incompletely lined with elongated, tapered cells arranged with their long axes parallel to that of the vessel, rather like the staves of a barrel. There is some disagreement about whether the cells lining the sinuses are modified reticular cells or endothelial cells,<sup>20,21,25,28,31</sup> but in any case their cell borders abut one another at their lateral surfaces, and there are no attachments or desmosomes, nor is there intercellular ce-

ment substance between them. As a result the lining cells may be easily separated, and small gaps between them are often seen through which blood cells traverse the sinus wall or pseudopods of macrophages extend (Figs. 8-5 and 8-6). A heavily fenestrated network of reticular, basement membrane fibers surrounds the sinus, like a roll of chicken wire, and these fibers anastomose with the reticular fibers of the cordal tissue. As already mentioned, the *splenic cords* lie between the sinuses. They consist of blind sacs, with no morphologically intact openings into the sinuses. The cords are filled with a meshwork of reticular cells together with extracellular reticulum quite similar to that of the white pulp with which they merge almost imperceptibly in the marginal zone. Between the reticular cells of the cords may be found a diverse cell population. Lymphocytes and monocytes are present in high concentration as are macrophages and erythrocytes; neutrophils and platelets are considerably less abundant.

### Blood Flow through the Spleen

Whether blood flow through the spleen follows anatomically discrete vascular channels ("closed" circulation) or empties into pulp areas and somehow traverses them to reach the sinuses via an "open" circulation has been the subject of controversy for years. Knisely, using quartz rod transillumination and microscopic observation of exteriorized spleens, saw no vessels opening out into or pouring blood into intercellular pulp spaces in living unstimulated spleens.<sup>23,24</sup> He described blood flow through a vascular system consisting of a series of completely interconnected, preformed channels as well as cyclic filling and emptying of the splenic sinuses, apparently regulated by afferent and efferent sphincters. For a time his studies appeared to settle the controversy in favor of the "closed" circulation. However, other workers using the same techniques<sup>25</sup> were unable to confirm Knisely's findings. This fact plus the inability of many workers<sup>20,21,25,29,30,31</sup> to find morphologically discrete channels on

careful light and electron microscopic study has resulted in rejection of the "closed" circulation theory and there is now general acceptance of the "open" circulation hypothesis. According to this, arterial blood is normally delivered to the marginal sinus, the marginal zone, and the red pulp (Fig. 8-2) and from here the blood rapidly traverses the intervascular zone. In the larger, most direct pulp channels, the rate of flow may be scarcely less than in the arterial capillaries. In the smaller, more devious passages, progress is slower and irregularly intermittent.<sup>26</sup> Thus, normally most of the blood appears to reach the sinuses by direct but anatomically undefined channels, and only a small proportion (<2%) slowly percolates through the labyrinthine cordal tissue. From the sinuses the blood flows directly into pulp veins and thence into trabecular veins. The blood supply to the white pulp comes from the radial branches of the central artery. The paucity of erythrocytes in the white pulp apparently results from plasma skimming at the right-angle branching of the radial arteries. These arteries divide into capillaries that arborize and finally terminate in the marginal sinus (Fig. 8-2).

### Erythrocyte Mixing in the Spleen

In man, radioactivity measurements over the normal spleen after the injection of <sup>51</sup>Cr-tagged, normal erythrocytes demonstrated a rapid, single exponential increase to equilibrium levels in from 15 seconds to 2 minutes<sup>103,120</sup> (Fig. 8-3). This and the fact that splenic mixing curves after injections of labeled red cells and labeled plasma were essentially identical<sup>27</sup> clearly demonstrated the lack of significant trapping of normal red cells in the normal human spleen.

In contrast, in animals, such as the cat, which have many muscle cells in the capsule and trabeculae, variation in blood content of the pulp is controlled by relaxation and contraction of the whole organ.<sup>28</sup> In such animals a double exponential, splenic mixing curve was seen after the injection of <sup>51</sup>Cr-labeled erythrocytes (Fig. 8-3) thus demonstrating a

Fig 8-3 Splenic red cell-mixing curves obtained after the injection of radioactively labeled, autologous erythrocytes into man (o) or the cat (•). Note the single exponential mixing curve in man and the two component curves in the cat (Idealized curves adapted from Pranker<sup>21</sup>)

considerable amount of splenic red cell pooling even in the normal state.<sup>27</sup> This splenic pool of red cells could be mobilized by the injection of  $\alpha$ -epinephrine.<sup>27</sup> A variety of stresses such as excitement, anoxia, hemorrhage, exercise, and electric stimulation or manipulation of the splenic pedicle also result in splenic contraction. In animals, splenic relaxation occurs after eating, in response to certain anesthetic agents, and to some degree in response to autonomic blocking agents.<sup>26,27</sup> Intermittent arterial constriction additionally regulates blood flow to areas of the pulp.<sup>26</sup> In man, however, autonomic blockade did not result in red cell pooling in the spleen,<sup>27</sup> and alteration in arterial vessel size is presumed to be the major mechanism for variations in splenic blood flow.<sup>23</sup>

### Platelet Mixing in the Spleen<sup>22</sup>

In normal man, after the injection of  $^{51}\text{Cr}$ -labeled autologous platelets, the splenic mixing curve, like that for red cells (Fig. 8-3), followed a simple exponential pattern.<sup>22</sup> However, the half time for platelet mixing in the spleen was 2.5 minutes and mixing was complete only after about 10 minutes. Another difference between erythrocytes and platelets is that, although there appears to be little or no splenic reservoir of erythrocytes in man, approximately 30% of the normal circulating mass of platelets resides in the spleen. These platelets can be expressed into the circulation during a slow infusion of epinephrine.<sup>22</sup>

### Changes in the Blood Following Splenectomy<sup>27,41,60,66</sup>

Since some of the functions of the spleen have been inferred from the changes in the blood which can be observed following splenectomy or are found when the spleen is congenitally absent, these will be considered first.

In man and in animals,<sup>50</sup> splenectomy results in changes in the morphologic structure of red cells and in the concentration of platelets and leukocytes. Similar changes occur both after the removal of the normal spleen (eg, trauma) and after removal of the spleen for treatment of pathologic states.

The most striking changes are seen in the red cells (Fig. 8-4). Nucleated red cells may appear in the circulating blood as well as corpuscles containing Howell-Jolly bodies; the percentage of reticulocytes may be increased<sup>41</sup> and siderocytes, diffuse basophilia, and target cells are found.<sup>41,52,60</sup> Autophagic vacuoles, which appear to develop even in normal erythrocytes, also accumulate in the blood in increased numbers.<sup>48</sup> These changes may be more striking when red cell production is stimulated or otherwise altered, as can be seen in splenectomized dogs or pigs in which anemia was produced by phlebotomy, the administration of acetylphenylhydrazine, or by pyridoxine deficiency.<sup>38,39</sup> For exam-

ple, in the splenectomized dog made anemic by bleeding or injections of acetylphenylhydrazine, the number of normoblasts in the blood was four times greater than in non-splenectomized animals.<sup>38</sup>

Howell-Jolly bodies are the most consistent finding in the blood following splenectomy. They are seen in all such patients and persist for years.<sup>60</sup> The erythrocyte volume remains normal after splenectomy, but the erythrocyte surface area is larger<sup>60,62</sup>; the corpuscles are thinner (leptocytes) and may take the form of target cells (see Chapter 3). The saline osmotic fragility of these cells is decreased<sup>60</sup>; however, when examined many years following splenectomy this often,<sup>41</sup> but not always,<sup>60</sup> has returned to normal. There appears to be no consistent change in erythrocyte or hemoglobin concentration after splenectomy,<sup>52</sup> both polycythemia (6 to

$7.5 \times 10^{12}$  cells/l) and anemia having been reported.<sup>41</sup> The latter is mild and usually is transient. Red cell life span is not detectably altered.

After splenectomy, *leukocytosis* occurs; it is usually modest ( $10.0$  to  $15.0 \times 10^9$  cells/l) and may occasionally be quite pronounced ( $30.0 \times 10^9$  cells/l). The maximum increase is reached during the first postoperative week, and is due chiefly to an increase of neutrophils. Patients examined three months or more after removal of the spleen showed slight to moderate leukocytosis, but this was due mainly to an increase in lymphocytes and monocytes and not to neutrophilia<sup>56</sup>; the same findings have been reported for rats.<sup>63</sup> Less consistently, eosinophilia and basophilia are found.<sup>52</sup> The postsplenectomy changes may persist for years.

*Thrombocytosis* occurs after splenectomy in

Fig 8-4 Photomicrographs of blood smears of patients splenectomized because of idiopathic thrombocytopenic purpura. Note the bizarre poikilocytes, the target cell (A), the Howell-Jolly body (B), the stippling (C), and the barely perceptible Pappenheimer bodies (D) (Wright's stain X 1270).

spleen,<sup>86</sup> differentiate into erythroid, myeloid, or megakaryocytic precursors, and protect the recipient from the fatal effects of the irradiation.<sup>107</sup> Presumably this hematopoietic potential is also present in man, is retained throughout life, and probably explains the *myeloid metaplasia* occasionally seen in patients with severe anemia, or with damaged or infiltrated marrows.

In contrast to the lack of neutrophil, erythrocyte, and probably platelet production in the normal human spleen, in normal rats extensive uptake of injected <sup>3</sup>HTdR by splenic mononuclear cells was demonstrated,<sup>97</sup> thus indicating new cell formation in these cell lines. In these studies, two labeling patterns were seen: (1) heavy grain counts in 2 to 4% of the medium-sized to large mononuclear cells in the red pulp and in the perfollicular regions (marginal and mantle zones) and (2) low grain counts (one half to one third of those seen in [1]) in 40 to 50% of germinal center cells in the lymphatic follicles. The perfollicular and red pulp labeling appears to reflect the formation of macrophages, lymphocytes, and plasma cells and is markedly increased after the injection of heat-damaged red cells<sup>9</sup> or antigenic material.<sup>74</sup> The cells in the germinal centers which showed extensive but low grain-count labeling may represent those which provide so-called "immunologic memory." In these sites, newly formed cells appear to die early, as judged by studies which revealed labeled pyknotic nuclei ("tingible bodies") in the germinal centers in less than one-half hour after <sup>3</sup>HTdR injection.<sup>97</sup> Furthermore, the observation that germinal centers develop in lymph nodes only on secondary immunologic stimulation<sup>90</sup> provides support for the concept that a mechanism for immunologic memory operates in the germinal centers.

In any case there are at least two different patterns of new mononuclear cell production in the normal spleen: (1) that in the perfollicular regions and red pulp and (2) that in the germinal centers of lymphoid nodules. This new cell formation is greatly accentuated in spleens stimulated to increase filtering activity, as by the injection of bacterial endo-

toxin,<sup>89,83</sup> methyl cellulose,<sup>104,124</sup> saccharated iron oxide,<sup>11</sup> polyvinylpyrrolidone,<sup>82</sup> zymosan,<sup>100</sup> phenylhydrazine, and heat-damaged or stored red cells.<sup>9</sup> Repeated injection of such materials into animals results in splenomegaly, and eventually a sustained increase in mononuclear cell proliferation occurs which resembles neoplasia.<sup>9</sup> The extent of increased cell proliferation is indicated by the tenfold increase in spleen weight that follows three to four months of phenylhydrazine administration and the 18- to 20-fold increase in DNA levels.<sup>9</sup> The facts that stored or heat-damaged autologous cells have the same effect<sup>9</sup> and that some patients with biochemical defects in their red cells (eg, hereditary spherocytosis, pyruvate kinase deficiency, certain hemoglobinopathies) may show evidence of increased cell proliferation suggest that the stimulus to cell proliferation is phagocytosis and increased filtration rather than immunologic. These findings led to the proposal that the total particulate load provides homeostatic regulation of the RES.<sup>108</sup>

### *Phagocytosis and Related Functions (Pitting and Culling)*

Electron microscopic examinations of the phagocytosis of carbon particles<sup>87</sup> have added considerably to our understanding of the process already described. Within a few seconds after injection the carbon particles were found in small clumps chiefly in the marginal sinuses, marginal zone, and adjacent red pulp. Phagocytosis by macrophages that extend cytoplasmic projections through the fenestrated basement membrane, between sinus endothelial cells, and into the sinuses could be seen during the first minute (Fig. 8-5). Phagocytosis by macrophages within the cords was also evident at this stage, and platelet aggregation around the particles and their ingestion were evident both in the sinuses and in the cords.<sup>87</sup> Carbon was rarely seen in neutrophils. Carbon was first seen in sinus endothelial cells after six minutes, and by one hour heavy concentrations became evident in individual macrophages, especially those immediately beneath the basement mem-

Fig 8-5 Electron microscopy of the marginal zone (MZ) of rabbit spleen 20 seconds after the injection of carbon particles. A macrophage (Ma) has projected a large pseudopod through gaps in the basement membrane (bm) and between endothelial cells (E). The carbon particles (small arrows) were found at the cell membrane adjacent to a marginal sinus (S). Phagocytosis of some particles (large arrow) was evident. Ly-lymphocyte. (From Simon and Burke,<sup>131</sup> courtesy of the authors and Harper & Row.)

brane. This concentration in splenic cord macrophages increased for at least a week and there was an associated decrease of carbon content in other organs during this interval. It was concluded that virtually all splenic phagocytosis was due to macrophages and that endothelial cells play a very minor role.<sup>67</sup> Interestingly, platelets seemed to play an important role in the clearance of carbon particles from the circulation, and this presumably

explains the reported decrease in platelet concentration after carbon ingestion.<sup>65</sup> The carbon aggregates accumulated within membrane-bound vacuoles in the macrophage cytoplasm.<sup>67</sup>

For many years the spleen has been regarded as the "graveyard" for effete and senescent blood cells<sup>132</sup> and this has been clearly established for red cells damaged experimentally and in a number of pathologic

states.<sup>131</sup> The clearance of erythrocytes severely damaged by complete or complement-fixing antibodies,<sup>83,109,111</sup> large doses of oxidant drugs,<sup>119</sup> sulfhydryl inhibitors,<sup>79,107</sup> heating,<sup>144</sup> or metal ions<sup>110</sup> appears to occur throughout the RES in a manner similar to the clearance of colloids. However, the spleen has been shown to have a special capability of trapping mildly damaged erythrocytes such as those treated with small amounts of antibody,<sup>109</sup> brief heating,<sup>144</sup> low doses of oxidant drugs,<sup>79,105,119</sup> or incomplete antibodies.<sup>109,111</sup> This unique ability of the spleen to detect minimal red cell damage or defects is presumed to depend upon its distinctive structure and vasculature in that cells traversing the tortuous cordal route are exposed to periods of stasis and come into intimate contact with splenic macrophages. Prolonged intrasplenic stasis in the cords exposes the erythrocytes to bemoconcentration, hypoglycemia, and low pH<sup>121,128</sup> and, as a result, spherocytosis and osmotic fragility are enhanced.<sup>79,119,120</sup> In mildly damaged or minimally defective cells this presumably leads to further damage of the cell membrane and, if the damage is of sufficient degree, phagocytosis follows. This "culling" process<sup>92</sup> occurs in the center of the cord.<sup>25</sup> Electron microscopic studies in normal rabbits demonstrated phagocytosis of intact whole erythrocytes, leukocytes, and platelets by macrophages in the peripheral white pulp and in the marginal zone of the splenic red pulp.<sup>138</sup> No morphologic change or fragmentation of these cells was seen outside the macrophages and after ingestion they underwent degradation in membrane-bound vacuoles. It seems possible that this process reflects normal disposal of effete blood cells in the spleen. This view is supported by studies in which a cohort of red cells was labeled by injecting <sup>59</sup>Fe into dogs and subsequently administering an excess of non-radioactive iron to obviate reutilization of the <sup>59</sup>Fe. When the radioactive erythrocytes were finally destroyed, much of the radioactivity was found in the spleen.<sup>96</sup> It has been suggested that the destruction of senescent blood cells is responsible for the maintenance of

spleen size in the normal state since splenic atrophy occurred in animals subjected to chronic phlebotomy.<sup>93</sup>

In contrast to the phagocytosis and destruction of entire cells ("culling" function), a "pitting" function of the spleen has been described.<sup>91</sup> "Pitting" refers to the ability of the normal spleen to remove particles from the intact red cell without destroying it. It was demonstrated that when blood containing a high proportion of siderocytes was transfused into recipients with intact spleens the siderotic granules were removed within several hours, but the cells, identified by <sup>51</sup>Cr labeling or immunologically, remained in the blood.<sup>91</sup> It has not yet been clearly shown that the siderotic granules are removed by "pitting," but by analogy with the removal of Heinz bodies (see below) this seems likely. The possibility remains that siderotic granule iron is also dispersed within the cell and eliminated by a metabolic process since this has been demonstrated to occur when post-phlebotomy, reticulated siderocytes are incubated *in vitro*.<sup>94</sup> On the other hand, reticulocytes induced by B<sub>6</sub> deficiency do not release their iron on incubation *in vitro* and therefore must be "pitted."<sup>102</sup>

Striking splenic sequestration of Heinz body-containing red cells (produced by phenylhydrazine injection into rabbits) and thalassemic red cells containing precipitated alpha chains of globin has been demonstrated<sup>130,139,143a,145</sup> and phagocytosis of many whole cells ensued. However, it was also shown that, as some of these damaged cells moved from the splenic cords into the sinuses, projections of cell cytoplasm, often containing the Heinz body or precipitated globin, lagged behind and were pinched off and phagocytized (Fig. 8-6).<sup>130,145</sup> This is the presumed mechanism of the "pitting" process that is thought to be unique to the spleen.<sup>25,139,145</sup> It is presumed that the same mechanism is responsible for removal of Howell-Jolly bodies, red cell nuclei, malarial parasites, bartonella organisms<sup>25</sup> and autophagic vacuoles,<sup>48</sup> but this has been less clearly documented.

A similar process appears to modify im-

Fig. 8-6. Electron microscopic view of the removal of phenylhydrazine-induced Heinz bodies in the dog spleen. The sinus lumen (SL) is above and the cordal lumen (CL) below with dark-red corpuscles seen in each. The fenestrated basement membrane can be seen with sinus endothelial cells (SE) lining the sinus lumen. A reticular cell (RC) and a phagocytic cell (Ph) are interposed between the cordal lumen and the basement membrane (BM) and the sinus lumen. Red corpuscles can be seen squeezing through the pores in the basement membrane and Heinz bodies (H) trailing behind and some of these have been pinched off and phagocytized (From Koyama et al.,<sup>25</sup> courtesy of the authors and *Mie Medical Journal*).

mature red cells<sup>101</sup> and stress reticulocytes.<sup>89</sup> Reticulocytes exhibit some of the properties manifested in erythrocytes coated with antibodies, namely, increased agglutinability (apparently related to coating with transferrin), and these cells are selectively trapped in the spleen.<sup>108</sup> Studies in which stress reticulocytes were labeled with glycine-<sup>14</sup>C (in heme) and radiophosphate (in membrane phospholipids) and then transfused into normal recipients demonstrated selective removal of labeled lipid with continued survival of the heme-labeled red cells.<sup>89</sup>

No similar "pitting" or "culling" functions

have yet been demonstrated for cells other than erythrocytes.

### Iron Metabolism

After sequestration and destruction of damaged or effete red cells, the spleen appears to be able to readily recycle the iron to the marrow to be used again for hemoglobin synthesis.<sup>25,92</sup> After splenectomy, serum iron values tend to be low for a considerable period of time, possibly because of loss of the spleen's iron-recycling function. Other organs that are sometimes involved in

hemoglobin breakdown, such as the epithelial cells of the renal tubules and the phagocytes of the lungs, do not seem to be capable of returning the iron to available body stores. When hemosiderin is deposited in the renal tubules, hemosiderinuria occurs and the iron is lost as the tubule cells are sloughed off in the urine. When bleeding occurs in the lungs, pulmonary siderosis develops and the iron is retained in macrophages, even in the face of iron deficiency anemia.

### *Antibody-Producing Function*

The importance of the spleen in antibody production has been appreciated for some years in that splenectomy was demonstrated to reduce the ability of animals<sup>75,133,135,146</sup> and man<sup>134</sup> to produce antibodies and to respond to small doses of soluble antigen. In more recent direct studies, spleen cells have been shown to produce antibody after the injection of, for example, sheep red cells<sup>74,81</sup> or poliovirus.<sup>141</sup> Autoradiographic study has shown that radioactively labeled antigens injected intravenously are rapidly taken up by phagocytes of the RES. After a single intravenous injection of bovine serum albumin or keyhole limpet hemocyanin into rabbits, much of the antigen localized in the liver but subsequently left the liver and was found in the spleen and to a lesser degree in lymph nodes.<sup>99</sup> A comparison of the localization of carbon particles and <sup>125</sup>I-labeled salmonella antigens after intravenous injection showed different distribution in the spleen depending on the time of evaluation.<sup>122</sup> Antigen was first found in the marginal zone and red pulp, but then appeared to concentrate in the marginal zone and move across the marginal sinus and into the white pulp, finally localizing in the cap of the lymphoid follicles. A similar but slower and less intense accumulation of antigen occurred after subcutaneous foot-pad injection, most of the antigen remaining in the regional nodes. Carbon particles also were found first in the marginal zone and red pulp. Later they moved to the periarterial white pulp and then to "tingible body" macrophages in the germinal centers. In all three

studies it appeared that discrete, particle-laden cells were redistributed after initial localization. The significance of these observations in relation to antibody formation is not entirely clear except that localization in lymphoid follicle caps of both the spleen and lymph nodes is much more intense in previously primed than in unprimed animals.<sup>117,118</sup> In any case, an early event after antigen localization was morphologic differentiation with increased numbers of plasma cells appearing as early as 13 hours after antigen injection.<sup>74</sup> Antibody could be detected (plaque formation method) by 72 hours, increased to a maximum at 96 hours, and serum antibody levels reached peak values 72 hours after that.<sup>74</sup>

In summary, the spleen is clearly involved in antibody production but the degree of involvement appears to vary with the type of antigen, the site of injection and the amount given. The spleen does not appear indispensable to antibody formation since antibody is formed in asplenic subjects. However, a delay in appearance and lower peak antibody titers are noted after splenectomy.<sup>75,133,134,135</sup>

### *Control over Hematopoiesis*

Ferrata believed that the spleen normally exerts an inhibitory effect on bone marrow activity. This possibility has intrigued investigators for years and was inferred from the blood changes demonstrable after splenectomy. However, as other explanations for many of these postsplenectomy changes have been provided, evidence for a direct (humoral) control over hematopoiesis has dwindled. Thus there is no evidence that the spleen influences the enzymatic synthesis of hemoglobin, porphyrins, or stromal proteins. Also the suggestion that the spleen determines the age at which young erythrocytes are released from the bone marrow and that postsplenectomy reticulocytosis results from removal of this control is now explained in another way, namely, that the normal spleen traps reticulocytes and after splenectomy these sticky, easily agglutinated young cells can circulate freely in the blood.<sup>101,108</sup> On the

other hand, the concept that the spleen might influence the stem cell population in the bone marrow<sup>92</sup> has been expanded, and it is now clear that in mice the spleen may serve as a source of colony-forming units (cells) capable of repopulating a depleted marrow.<sup>86</sup> Also it has been suggested that homogenates of mouse spleen enhanced recovery from irradiation and increased the number of hematopoietic stem cells in the marrow.<sup>112</sup> That this may not represent specific control over hematopoiesis is suggested by the fact that an increase in hematopoietic stem cells as measured by endogenous spleen colony formation can be produced by injection of foreign plasma, endotoxin, and a variety of other substances.<sup>85</sup> Thus it remains to be demonstrated that there is a specific splenic humoral controlling substance.

There is evidence that the spleen may exert some control on leukocytes in that the leukocytosis that develops following splenectomy in normal animals is much more pronounced than that occurring after other operations.<sup>123</sup> It was shown that the usual postsplenectomy leukocytosis can be prevented by leaving 25% of the organ intact within the body, or by transplanting as little as 10% of a spleen that had been removed.<sup>123</sup> Furthermore, when splenectomy was performed in one partner of parabiotic rats, no rise occurred in the leukocyte count of either animal; only when the spleen of the second partner was removed did a rise in the leukocyte count take place and this occurred in both animals. That a splenic humoral factor may exist<sup>126</sup> is also suggested by observations of the effects of splenectomy and reimplantation of splenic tissue.<sup>142</sup> These observations suggest that the rate of production or liberation of leukocytes from the marrow may be under the control of the spleen, but other explanations are possible and no splenic humoral "leukopoietin" has yet been demonstrated. There is some evidence that the spleen is a source of granulocyte colony-stimulating activity, but not the sole source.<sup>137</sup>

The well-known observation that radiation directed to the spleen is associated with a reduction in circulating leukocytes in leuke-

mic patients has led to speculation that a humoral factor liberated by the spleen in response to roentgen therapy causes this decrease. Studies of the effects of the reinjection of plasma drawn before and after irradiation of the spleen provided support for this hypothesis.<sup>115</sup> However, attempts made from time to time to demonstrate inhibitory effects of splenic extracts on hematopoiesis have yielded only equivocal results.<sup>76,125</sup>

Postsplenectomy thrombocytosis, as already discussed (page 359), appears to be explainable on the basis of removal of the normal storehouse for about one third of the blood platelets.<sup>77</sup> No splenic thrombopoietic activity has yet been demonstrated.

Disorders of the spleen and methods for their study, including splenic puncture, are discussed in Chapter 45.

## SECTION 4: Platelets, Hemostasis, and Coagulation

Hemostasis has been defined as "the process which spontaneously arrests the flow of blood from vessels carrying blood under pressure."<sup>244</sup> Few biologic processes are of more immediate and critical homeostatic importance. In all animals, including even the invertebrates, hemostasis is normally accomplished by a combination of three processes, ie, the contraction of the vessels, the adhesion and aggregation of formed blood elements such as the amebocyte or platelet, and the process of blood or plasma coagulation.<sup>244</sup> In man these vascular, cellular, and biochemical hemostatic functions have evolved to a high degree of complexity. All three are required for completely efficient hemostasis, but they are homeostatically independent to the extent that hemostasis compatible with life is maintained even if one component, such as the platelets or a single coagulation factor, is deficient.

Despite their physiologic importance, the processes of platelet aggregation and blood coagulation may constitute a threat to the organism if they propagate beyond the wound site. They normally are kept within desirable limits by various homeostatic control mechanisms. Once the function of the hemostatic barrier has been served, fibrin is removed by the fibrinolytic enzyme system and the leukocytes, a process which leads to recanalization of the damaged vessels.

In the next two chapters, hemostasis and the various homeostatic control mechanisms will be discussed under three headings, namely, the functions of the vessels, the platelets, and the coagulation mechanism. The events of the vascular and platelet phases, which together produce the first or temporary hemostatic barrier (*primary hemostasis*), will be considered in the following chapter (Chapter 9). *Secondary or permanent hemostasis* requires the formation of fibrin. This protein is the product of the coagulation phase, which, together with the fibrinolytic enzyme system, is discussed in Chapter 10.

These various phenomena will be considered in this volume mainly in terms of their role in hemostasis. However, with advancing knowledge it has become apparent that they are intimately related to other defense mechanisms, eg, vascular permeability, inflammation, wound healing, the action of the complement system and other immunologic reactions.<sup>172,291,294,298</sup>

Much of what has been learned about abnormalities of coagulation, platelet dysfunction, and quantitative variations of platelets in disease is pertinent to a knowledge of normal hemostasis and blood coagulation. Thus, the information presented in Part IV (page 1040) serves in many ways to supplement the following discussion.

aspects of the role of the platelet in coagulation. The following information concerning the platelet is discussed elsewhere: its antigenic structure (Chapter 12), methods for *in vitro* preservation and the therapeutic use of platelet transfusions (Chapter 12), techniques for enumeration and for assessing various individual platelet functions (Chapter 33).

## **The Blood Platelet**

In the early part of the 19th century, many investigators observed the blood platelets,<sup>411</sup> but even Zimmermann (1860), Max Schultz (1865) and Osler (1874), who realized that these particles were not artifacts, failed to recognize their true importance. Hayem (1878), like Zimmermann, thought that they developed into red blood cells. It remained for Bizzozero<sup>42</sup> (1882) to describe platelets as they appeared in the mesenteric vessels of rabbits and guinea pigs. He demonstrated their adhesive quality, their participation in thrombi, and their role in the coagulation of the blood. The origin of the platelet from the megakaryocyte was established by the important studies of Wright.<sup>448</sup>

### **Morphology**

The morphology of platelets varies greatly depending on the methods by which they are examined, the anticoagulant, and the temper-

**T**HE present chapter will summarize information concerning the platelets, their precursor cell—the megakaryocyte, and the phenomena of primary hemostasis, including, for convenience, the events of the vascular phase. The discussion of platelet function will include the effects of the products of coagulation on platelets, and certain

ature.<sup>259</sup> In *wet preparations*, platelets are colorless, moderately refractile bodies that are discoid or elliptical in shape. Under dark-field illumination they are translucent, and reveal a sharp contour. A few immobile granules are present in the center of the cell. When observed by phase contrast microcinematography, contractile vacuoles and vacuoles of pinocytosis have been noted.

In *smears* stained by one of the Romanowsky methods, platelets appear round, oval, or rod-shaped. Azurophilic granules are seen in a hyaline, light-blue cytoplasm. These granules may be so tightly packed in the central portion of the platelet that they give the appearance of a nucleus. To the granular and hyaline portions the terms "granulomere" and "hyalomere" have been applied, respectively, but instantaneous fixation and staining with dyes like brilliant cresyl blue fail to show a sharp division into two portions. The platelet granules stain with neutral red; a few mitochondrial rods and granules stain with Janus green.

The dimensions of the platelet, as determined by electron microscopy, average 1.5  $\mu\text{m}$  in diameter and from 0.5 to 1  $\mu\text{m}$  in thickness.<sup>192</sup> The determination of platelet size by conventional microscopic techniques is fraught with many difficulties.<sup>259</sup> Estimates of platelet volume obtained by older "thrombocytocrit" methods<sup>330</sup> are erroneously high due to the marked platelet swelling which may occur rapidly in certain anticoagulants and at temperatures below 37°C.<sup>65</sup> As determined by means of an electronic particle counter, modal platelet volume ranges from 5 to 6  $\mu\text{L}$ ,<sup>363,364</sup> but it has been suggested that the assumptions upon which impedance counting are based may not be entirely valid in the case of platelets.<sup>52</sup>

A qualitative estimate of platelet volume, and thereby of their number, may be obtained by observing the thickness of the platelet layer in a hematocrit that has been centrifuged after sedimentation has taken place. If a hematocrit filled with blood is allowed to stand an hour or longer, the red cells settle to the bottom, the leukocytes settle more gradually, and the platelets remain suspended

in the plasma. If centrifugation is then carried out, slowly at first and then more rapidly, three layers may be seen, namely, a creamy-white layer of platelets, a reddish-gray layer of leukocytes, and a red layer of erythrocytes (Plate 1, Frontispiece, and Fig. 3-20, page 112). This method serves only as a rough guide because some platelets remain in the plasma in spite of centrifugation and others are intermixed with the leukocytes.

### Ultrastructure

The platelet membrane is approximately 7.5 nm thick, and has a trilaminar unit structure<sup>53, 432</sup> (Fig. 9-1). Although it has been suggested that it is derived from endoplasmic reticulum of the megakaryocyte,<sup>53</sup> most evidence favors the view that it is a derivative of the plasma membrane of the parent cell, and thus resembles the external membranes of most other cells.<sup>22, 29</sup> External to the membrane is the *surface coat*, a "fuzzy," irregular layer ranging from 10 to 50 nm in thickness which is clearly revealed only by means of special fixation and staining procedures.<sup>432</sup> It is composed of a variety of proteins and mucopolysaccharides and contains a high concentration of sialic acids.<sup>313</sup> This coat may represent the adsorbed "plasmatic atmosphere"<sup>335</sup> or a true component layer of the cell membrane.<sup>463</sup>

The *marginal microtubular system* consists of 5 to 10 structures, approximately 20 nm in diameter, which encircle the periphery of the cell (Fig. 9-1). First revealed by the technique of double fixation,<sup>367</sup> these structures appear to contain thrombosthenin,<sup>462</sup> and under certain circumstances seem to undergo a reversible depolymerization into smaller microfibrils 7 nm in diameter.<sup>23, 423, 462</sup> The changes that occur in the microtubules during platelet aggregation and the location of these structures within the platelet suggest that they function as both the platelet "cytoskeleton"<sup>30, 428</sup> and the intrinsic contractile apparatus.<sup>28, 269, 366, 462</sup> A second microtubular system (the *dense tubular system*) is closely associated with the marginal microtubules.<sup>29</sup>

The *surface-connecting tubules* (canalicular

**Fig 9-1.** Ultrastructure of human blood platelets. *Left*, Thin section of human platelet. Mitochondrion (M), marginal microtubules (MT), dense tubular system (DTS), dense body (DB), glycogen (Gly), granule (G), canalicular system (OCS) (From White<sup>433</sup> courtesy of the author and the *Annals of the New York Academy of Sciences*) *Below*, Section of a platelet fixed after incubation in distilled water for five minutes at 37°C. Microfibrils have become apparent in the cytoplasm. Microtubules (arrow) are intact. Note the unit membrane and surface coat  $\times 60,000$  (From Zucker-Franklin,<sup>462</sup> courtesy of the author and the *Journal of Clinical Investigation*)

system) are a network of vesicles and interconnecting channels which ramify throughout the entire cytoplasm and communicate with the cell surface. This system is lined with the same membrane and surface coat that covers the external surface of the platelet, and is found in close apposition to storage organelles, eg, "dense bodies."<sup>432</sup> This and other observations<sup>136</sup> suggest that the release reaction may occur through openings formed by fusion of the limiting membrane of the

storage organelles with that of the external membrane and the canalicular system.<sup>433a</sup> This tubular system also appears to be involved in platelet phagocytosis (page 400). The cytoplasm of the platelet contains masses of microfilaments (Fig. 9-1).<sup>136,384,464</sup>

**Granules and other organelles** (Fig. 9-1) include small mitochondria with 2 to 3 cristae,<sup>192</sup> glycogen granules,<sup>371</sup> lipid-filled inclusions, ferritin granules ("siderosomes"), and, in an occasional platelet, a Golgi appara-

tus.<sup>338</sup> Platelet ribosomes are very difficult to identify microscopically, but have been demonstrated in small numbers in cell homogenates.<sup>398</sup> Various electron-dense granules also are present; these vary greatly in appearance depending on the technique of fixation. The *alpha granule* is oval in shape and 0.15 to 0.4  $\mu\text{m}$  in greatest diameter.<sup>192</sup> Its membrane structure and contained acid phosphatase suggest that it is a lysosome.<sup>269,432</sup> This hypothesis has been questioned,<sup>380</sup> but is consistent with alterations that have been observed in platelets during storage.<sup>131</sup> Laminar structures which resemble phospholipid micelles also have been demonstrated in the *alpha granules*, and may represent platelet factor 3 (page 397).<sup>435</sup> However, quite similar structures have been encountered in various degenerating cells.<sup>192</sup>

The *platelet dense body* (dark body, "bull's-eye" granule, "very" electron-dense granule) is a round structure, 0.05 to 0.15  $\mu\text{m}$  in diameter, which is often embedded within granular matrix of distinctly less electron density or may be seen within small vacuoles. These storage and secretory organelles appear to develop from undifferentiated platelet granules,<sup>269,432</sup> and contain nucleotides, calcium ions, catecholamines, and possibly platelet factor 4<sup>104,269</sup> (page 398). It is probable that some authors use the terms "*alpha granule*" and "*dense body*" interchangeably.

### Variations in Size and Morphology

Attempts have been made to classify platelets on the basis of size<sup>265</sup> and other criteria,<sup>210,329</sup> but these features are highly variable and difficult to quantitate by simple microscopic methods.<sup>259</sup> Methods based on electronic sizing<sup>65,364</sup> and density gradient centrifugation<sup>16</sup> are more promising, but a "differential" classification of platelets is, at best, fraught with much difficulty.

There is good evidence that young platelets are larger and more dense than older cells.<sup>11,213</sup> Thus, platelet anisocytosis and macrocytosis are present when platelet production is accelerated. The number of abnormally large platelets ( $>2.5 \mu\text{m}$  in diameter)

bears a direct relationship to the number of megakaryocytes, an observation which may be clinically useful<sup>140</sup> (Chapter 34). These changes may be marked in disorders characterized by accelerated platelet destruction, eg, autoimmune thrombocytopenias (Chapter 34). In such disorders, platelets with very coarse granules, "basophilic" platelets, and forms with diminished granulation have been reported. In neonates, there may be more variation in the size of platelets and in their staining reaction than is normal in adults. In dogs, "reticulated" platelets have been demonstrated following acute blood loss.<sup>200</sup>

Large and bizarre platelets often are present following splenectomy (page 359), in myelofibrosis (Chapter 57), hemorrhagic thrombocythemia (Chapter 34), and in polycythemia vera (Chapter 30). Certain disorders of platelet function associated with thrombocytopenia are characterized by particularly large "giant" platelets (Fig. 35-3, page 1126). In other disorders, normal numbers of totally agranular platelets or abnormally small platelets may be seen (Chapter 35).

All of these changes in platelet morphology must be distinguished from very similar artifacts which arise in poorly collected blood specimens and in stored anticoagulated specimens.

### Biochemistry of the Platelet

From an "inert particle" that at one time was even thought to be an artifact, the platelet has emerged as a most remarkable structure which possesses abundant metabolic equipment, including more than 80 different enzymes,<sup>95,239</sup> significant synthetic capability, a capacity to expend considerable energy, and, like muscle, the ability to contract when appropriately stimulated.<sup>207</sup>

The chemical composition of the platelet (Table 9-1 and page 388) is difficult to determine accurately because of the tendency of this cell to adsorb a variety of substances from the plasma, the fact that centrifugation and washing may induce rapid and irreversible biochemical changes, and because of variations in its biochemical properties which depend on the age of the cell.

In terms of dry weight, the platelet is composed of approximately 60% protein, 15% lipid, and 8% carbohydrate. Important minerals include Mg,<sup>454</sup> Ca,<sup>454</sup> K,<sup>454</sup> and Zn.<sup>133</sup>

Copper and the heavy metals are absent.<sup>259</sup> Platelets contain substantial amounts of vitamin B<sub>12</sub>, folic acid, and ascorbic acid.<sup>425</sup>

Except where cited, data obtained from Maupin<sup>259</sup>

The sodium and potassium concentrations within the platelet are 39 and 138 mEq, respectively.<sup>147</sup> This gradient against plasma is maintained by an active ion pump, which derives energy from a membrane adenosine triphosphatase of the ouabain-sensitive,  $\text{Na}^+/\text{K}^+$ -dependent type.<sup>81,147</sup>

### Energy Metabolism

The similarities between the energy metabolism of the platelet (Fig. 9-2) and that of skeletal muscle have been emphasized repeatedly.<sup>216</sup> Both involve active glycolysis and the synthesis and utilization of large amounts of glycogen,<sup>218</sup> and in both the major mediator of intracellular energy utili-

zation is an actomyosin-like adenosine triphosphatase. The platelet, like muscle, is metabolically adapted to expend large amounts of energy rapidly, ie, during aggregation, the release reaction, and clot retraction.

The major energy source for the platelet is glucose, which is rapidly taken up from the plasma (Fig. 9-2). Under basal conditions, 40 to 50% of the absorbed glucose is used to provide energy for synthetic functions or is converted into glycogen,<sup>212</sup> which provides an endogenous store of carbohydrate.<sup>215</sup> Fatty acids also are metabolized.<sup>79,112</sup>

The glycolytic pathway with its regulatory enzymes (phosphorylase,<sup>217</sup> hexokinase,<sup>357</sup> phosphofructokinase<sup>107</sup>), the tricarboxylic

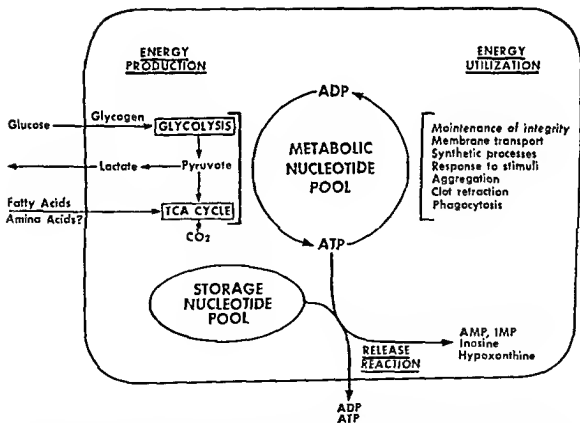

Fig 9-2. Simplified scheme of platelet energy metabolism. Platelet energy is derived from the metabolism of glucose and to a lesser extent from the metabolism of fatty acids. Energy is provided in approximately equal amounts by glycolysis and the tricarboxylic acid cycle. The platelet energy reserve is provided by the metabolic pool of platelet nucleotides that are in a state of continuous turnover. This energy is utilized for the maintenance of the platelets' structural integrity and in the reactions accompanying the response of platelets to stimuli. The granule-bound storage (nonmetabolic) nucleotide pool is discharged during the release reaction. (From Hirsh and Doery<sup>122</sup> courtesy of the authors and Progress in Hematology.)

acid cycle, the pentose-phosphate pathway, and the NAD-NADH system<sup>74</sup> are all active in the platelet.<sup>239</sup> Under normal circumstances, glycolysis is more active than oxidation, but the total ATP synthesized by the two pathways is approximately equal because of the greater ATP yield per mole of glucose provided by the latter.<sup>112, 212</sup> "Stimulation" of the platelet by agents that induce aggregation and the release reaction is associated with a marked increase in metabolic activity involving glycogenolysis and both glycolytic and oxidative pathways to variable degrees.<sup>172, 212, 231, 456</sup>

The ATP content of the platelet is 150 times that of the red cell (Table 9-1). Adenine nucleotides comprise 90% of free platelet nucleotide, and are synthesized from both adenine and adenosine. The platelet lacks the capacity for *de novo* nucleotide synthesis.<sup>181</sup> During the release reaction, approximately 50% of the platelet nucleotides are lost from the cell without impairing its metabolic viability. This is due to the fact that platelet nucleotides are partitioned into at least two different pools (Fig. 9-2).<sup>178, 184</sup> The *metabolic pool* is utilized for the maintenance of the various energy-consuming cell functions. Comprised largely of ATP, this pool is constantly turning over, as revealed by the rapid incorporation of <sup>14</sup>C-adenine and <sup>32</sup>P-phosphate into ATP.<sup>178</sup> The *storage pool* contains both ADP and ATP, is metabolically inactive, and does not incorporate exogenous adenine or phosphate. Nucleotides in this pool are extruded from the cell during the release reaction. There is preliminary evidence that the nucleotides in the storage pool are bound to thrombosthenin.<sup>185</sup>

The ATP that is broken down to provide energy for the release reaction is not rephosphorylated but, rather, is degraded (Fig. 9-2), an observation suggesting that both high-energy bonds have been utilized.<sup>184</sup> This ATP may be compartmentalized in a third pool that is in equilibrium with the metabolic pool.<sup>184</sup>

The role of cyclic AMP in the regulation of platelet function and energy metabolism

is discussed on page 395. The energetics of clot retraction are discussed on page 399.

## Proteins

The platelet has been likened to a sponge<sup>7</sup> because of its remarkable propensity to adsorb various substances from the plasma. These include proteins, amino acids,<sup>433</sup> histamine,<sup>269</sup> ions, and various drugs.<sup>292</sup>

Twenty *amino acids* have been identified in the platelet.<sup>259</sup> Of these, glycine, glutamic acid, alanine, serine, and aspartic acid are present in the highest concentrations.<sup>150, 259</sup> Taurine is present in concentrations averaging 200 times those of plasma (Table 9-1); its physiologic significance is uncertain.<sup>269</sup>

As many as 20 different proteins have been demonstrated in platelet homogenates by means of polyacrylamide gel electrophoresis,<sup>240</sup> but the differentiation between those that are nonspecifically adsorbed and those that are intrinsic to the cell is often difficult. Several have been identified immunologically, including thrombosthenin, albumin, prealbumin, IgG and IgM globulins,<sup>300</sup> plasminogen,<sup>99</sup> and fibrinogen.

*Fibrinogen*, in both an adsorbed and a granule-bound form, has been demonstrated in platelets.<sup>69, 149</sup> This protein also has been demonstrated in the megakaryocyte.<sup>145</sup> Data suggesting that platelet fibrinogen is biochemically different from plasma fibrinogen<sup>99, 138a</sup> have been disputed.<sup>94, 139</sup> Fibrinogen is an essential cofactor for ADP-induced platelet aggregation (page 391) and possibly is involved in other platelet functions.<sup>374a</sup>

Virtually all of the other *plasma coagulation factors* have been demonstrated in association with the platelet.<sup>172</sup> The vitamin K-dependent factors (prothrombin, factors VII, IX and X) appear to be weakly adsorbed and are readily removed by washing.<sup>108, 199</sup> whereas factors V, VIII,<sup>211</sup> XI, and XII<sup>189, 199</sup> appear to be more firmly bound. As much as 50% of the factor XIII in blood is associated with the platelets, and there is convincing evidence that this factor is synthesized by

the megakaryocyte and is not adsorbed from the plasma.<sup>261</sup>

There is much to suggest that the proteins present on the surface of the platelet ("*the plasmatic atmosphere*") and their interactions with those which coat vascular surfaces are important in platelet function.<sup>21,362</sup> Fibrinogen, as discussed above, factor XII,<sup>247</sup> and other as yet unidentified proteins<sup>90,110</sup> appear to have specific functional importance in platelet aggregation and in the release reaction. The interaction of the platelet with synthetic surfaces and particles can be specifically conditioned by various protein coatings.<sup>263,296,336,439</sup> Preliminary experiments with carefully washed platelets suggest that a balance between adsorbed anionic proteins and various cationic proteins, such as IgG immunoglobulin, factor XIIa, and fibrinogen, may be important in maintaining an optimal charge at the platelet surface.<sup>21</sup>

Platelets are able to synthesize both amino acids and proteins.<sup>423</sup> <sup>14</sup>C-labeled acetate and glucose are rapidly incorporated into glutamic acid, aspartic acid, glutamine, and asparagine,<sup>350</sup> while isotopically labeled amino acids are rapidly incorporated into platelet proteins, including fibrinogen<sup>85</sup> and thrombosthenin.<sup>399</sup> Protein synthesis takes place principally in young platelets.<sup>46,433</sup> These observations are noteworthy, since the platelet contains negligible DNA and the RNA present is in a metabolically inactive form. It has been suggested that protein synthesis is the result of residual stable messenger RNA<sup>45,46</sup> or possibly occurs in the mitochondria.<sup>151</sup>

**Thrombosthenin**, a contractile protein complex comprising 15 to 20% of total platelet protein, can be dissociated into two fragments which resemble actin (*thrombosthenin A*) and myosin (*thrombosthenin M*) of skeletal muscle.<sup>34,35</sup> The subunit molecular weights of these two fragments have been estimated at 46,000 and 200,000, respectively.<sup>9</sup> Under the electron microscope, thrombosthenin A appears as a rod-shaped molecule approximately 6 nm long and 0.1 to 0.2 nm thick.<sup>31</sup> It reveals an axial periodicity of 3.5 nm.

Thrombosthenin M is composed of large spindle-like structures, 0.2 to 0.5 nm long,<sup>31</sup> that presumably are polymeric in nature.<sup>35</sup> The "thrombin-sensitive" protein of the platelet membrane apparently is identical to thrombosthenin M.<sup>20,47</sup> Detailed studies of thrombosthenin M have revealed functional properties that are identical with myosin purified from skeletal muscle.<sup>9</sup> This evidence would seem to justify the conclusion that thrombosthenin is identical to the actomyosin system of muscle, as was first hypothesized many years ago.

In platelet homogenates, thrombosthenin is found almost entirely in the membrane and granule fraction.<sup>302</sup> Ultrastructural studies would suggest that it is associated with the marginal microtubular system<sup>35,68</sup> and perhaps with other organelles as well.<sup>137</sup> Quantitative assays of thrombosthenin by means of highly sensitive radial immunodiffusion techniques have revealed two fractions. That present throughout the cytoplasm (*thrombosthenin C*) comprises 90% of the total, while the remainder is located on the surface of the platelet (*thrombosthenin S*). Both of these fractions have adenosinetriphosphatase activity of the  $Mg^{++}/Ca^{++}$ -dependent type. Adenosinetriphosphatases which differ from thrombosthenin also are present in the platelets.<sup>302,431</sup>

The contraction of thrombosthenin underlies the phenomenon of clot retraction, and may explain the initial change in platelet shape produced by ADP, as well as the "cohesion" of secondary aggregates. It may also be involved in platelet aggregation (page 396).

### Lipid Metabolism

Platelets synthesize both fatty acids and phospholipids. <sup>14</sup>C-acetate and palmitate are incorporated into various platelet lipids.<sup>126</sup> <sup>432</sup> A high percentage of the label is initially present in free fatty acids in the platelet membrane<sup>432</sup>; these are synthesized both *de novo*<sup>435</sup> and by means of chain elongation, and are freely exchangeable with plasma fatty acids.<sup>109</sup> Phospholipids comprise 80% of the

total platelet lipid<sup>250</sup> (Table 9-1). Both <sup>14</sup>C-labeled fatty acids<sup>76</sup> and <sup>32</sup>P-phosphate<sup>312</sup> are incorporated into platelet phospholipids.<sup>397</sup> The turnover rate of these compounds, which normally is relatively slow, is significantly accelerated when platelets are "stimulated" by collagen, ADP, or thrombin.<sup>238a,312</sup> The phosphatidyl inositols, in particular, are heavily labeled under these circumstances, as in leukocytes during phagocytosis.<sup>312</sup> Significant concentrations of arachidonic acid, the precursor of prostaglandin PGE<sub>2</sub>, also have been demonstrated in the platelet.<sup>111</sup>

The role of platelet lipids in blood coagulation is discussed on page 397.

### Carbohydrates

The carbohydrates of platelets consist mainly of glycogen (Table 9-1). Heterosaccharide complexes containing sialic acids are abundant in the platelet membrane and surface coat,<sup>246,343</sup> and are important determinants of the surface charge. They also serve as acceptor sites for enzymes that may be involved in platelet adhesion<sup>202</sup> (page 391). Small amounts of glycolipids (gangliosides) also are present.<sup>254</sup> These compounds, and the sialoglycoproteins, are probably of importance in receptor sites for active transport functions.<sup>246</sup> Sulfated mucopolysaccharides<sup>319</sup> and a number of monosaccharides<sup>417</sup> are present as well.

### Origin of the Platelet

J. H. Wright concluded in 1906 that platelets are detached portions of the cytoplasm of megakaryocytes.<sup>418</sup> Wright's observations in cats were confirmed in other mammals by Bunting,<sup>66</sup> Downey,<sup>113</sup> and others,<sup>235</sup> and his theory is now generally accepted.<sup>226</sup> More recent evidence for this hypothesis may be summarized as follows: (1) platelets are first observed in the embryo at about the same time as megakaryocytes appear; (2) experimentally induced thrombocytosis is associated with an increase in the number of megakaryocytes; (3) there are numerous simi-

larities between the cytochemical<sup>239,410,450</sup> and antigenic<sup>418</sup> composition of megakaryocytes and platelets; (4) radioactive isotopes that are incorporated into megakaryocytes are subsequently found in the platelets; and (5) platelet production from megakaryocytes has been observed directly in animals.<sup>33,171,225</sup>

## The Megakaryocyte

### Morphology and Histogenesis

Megakaryocytes (Plate VIII, page 382; Fig. 9-3) are exceedingly large cells ranging from 35 to 160  $\mu$ m in diameter. They contain an irregularly lobed, ring- or doughnut-shaped nucleus composed of dense chromatin and staining brilliant blue with Wright's stain. Nucleoli are not seen. The cytoplasm is abundant and light blue, and is packed, except for a narrow rim at the periphery, with fine azurophilic granules. In the fetus, megakaryocytes are found successively in the liver, spleen, and bone marrow. In adult mammals they are precot in the bone marrow, lung, and spleen.<sup>153</sup>

The identification of normal megakaryocytes seldom is difficult, but occasionally these cells may be confused with other giant cells (Plate II, page 72), including those that are normally present in the marrow in small numbers (osteoclasts, osteoblasts, reticulum cells, rarely multinucleated erythroblasts and plasma cells), and pathologic cells (tumor cells, Reed-Sternberg cells, "storage cells").<sup>352</sup>

### Origin

Megakaryocytes have been considered to arise from a number of sources including primitive mesenchymal cells (Maximow), reticulum cells (Sabin), hemocytoblasts or large lymphocytes,<sup>410</sup> and from cells lining the sinusoids of the liver.<sup>5</sup> However, the evidence is now convincing that they originate, in common with erythrocytes and granulocytes, from the pluripotential stem cell. This is discussed on page 49.

Fig. 9-3 Megakaryocyte in material aspirated by sternal puncture Wright's stain  $\times 650$ . A metamyelocyte and a large normoblast as well as erythrocytes are shown for comparison of size.

### Development

The first morphologically recognizable precursor is the *megakaryoblast* (Plate VIII, page 382). This cell is 15 to 50  $\mu\text{m}$  in diameter and contains a large, oval or kidney-shaped nucleus with several nucleoli. The cytoplasm is scanty, nongranular, and intensely basophilic. Mitoses may be seen. The megakaryoblast enlarges, cytoplasmic granules begin to appear, and the *promegakaryocyte*, a cell 20 to 80  $\mu\text{m}$  in diameter, is formed. The nucleus of this cell is oval or irregular in shape; the cytoplasm is more abundant than that of the megakaryoblast and contains granules that develop first in the perinuclear zone. From this precursor, the *mature granular megakaryocyte*, described above, is formed. The terms *stages I, II and III* are often used with reference to the degree of maturity of megakaryocytes, and correspond, in general, to the designations megakaryoblast, promegakaryocyte, and granular megakaryocyte, respectively.

A qualitative assessment of the number of megakaryocytes relative to other marrow elements usually is sufficient for clinical purposes. This is done most quickly by scanning the smear with the microscope's low-power lens, which will clearly reveal these giant

cells. Megakaryocytes usually are most numerous in bone marrow "particles," and the number normally present in a bone marrow smear varies greatly depending on the relative cellularity of the specimen. The estimation of megakaryocyte numbers in hypocellular specimens is difficult. Quantitative methods for megakaryocyte enumeration are discussed below.

### Variations in Megakaryocyte Morphology

The morphology of the megakaryocyte normally is quite variable in stained smears. Some observers distinguish "reserve" megakaryocytes from platelet-producing forms on the basis of the absence of granules in the periphery of the cell.<sup>352</sup> Apparent "platelet production" from immature or nonfunctioning megakaryocytes may be due to artifacts, eg, "pseudothrombocytes" formed by shearing of a viscous cell coating during preparation of the smear,<sup>370</sup> the adhesion to the megakaryocyte of platelet aggregates formed from contaminating blood. Degenerating megakaryocytes, often surrounded by neutrophils, occasionally are seen in normal marrow.

When platelet production is accelerated,

megakaryocytes increase both in size and in number. In various forms of thrombocytopenia caused by accelerated platelet destruction, one may see immature forms that are not present in normal marrow, as well as morphologically abnormal and degenerating megakaryocytes and megakaryocytes that do not appear to be producing platelets (Plate XIV, page 1082). A differential count of megakaryocytes may have some value in such disorders,<sup>352</sup> which are discussed further in Chapter 34.

Abnormally large, hyperlobulated megakaryocytes with thin nuclear chromatin have been described in disorders caused by deficiency of folic acid or vitamin B<sub>12</sub><sup>352</sup> (Chapter 14). Numerous morphologically abnormal megakaryocytes often are present in myelofibrosis (Chapter 57). These are best seen in marrow specimens obtained by biopsy.

### Mechanisms of Platelet Production

Megakaryocytes are situated in the bone marrow in close proximity to the sinusoidal membrane.<sup>136</sup> Platelet production may occur by two somewhat different processes, both of which have been demonstrated in man.<sup>400</sup> Pseudopodial platelet formation, lucidly described by Wright,<sup>448</sup> has been demonstrated in several species by more modern techniques, eg, microcinematography in bone "windows" of rabbits.<sup>32</sup> Platelet formation begins by the development of numerous long cytoplasmic pseudopods that extend through apertures in the sinus membrane into the lumen, much in the manner of an octopus. These pseudopodia become thinner and ultimately filiform, and granular masses the size of platelets form within them. These processes probably are caught in sinusoidal capillaries, segments are broken off by their contraction, and the platelets thus formed are swept away by the blood stream.

Platelets are also formed by the *in situ* fragmentation of large portions of megakaryocyte cytoplasm. As visualized by electron microscopy,<sup>419</sup> this begins with the formation of "demarcation zones." These first appear as a chain of small vesicles that fuse to form fissures. The simultaneous widening

and fusion of these fissures result in the splitting of the megakaryocyte cytoplasm into 2000 to 4000 discrete units, the platelets. This process may involve large masses of cytoplasm simultaneously, or may occur by means of continuous demarcation of smaller areas.<sup>68</sup> Virtually the whole cytoplasm of the megakaryocyte is eventually broken away, and the bare nucleus remains to degenerate.

### Extramedullary Megakaryocytes

#### Lungs

It has been generally assumed that the main site of platelet production during adult life is in the bone marrow. Although megakaryocytes are normally found in the lungs, it was assumed that these were effete cells. Howell and Donabue<sup>196</sup> challenged this view on the following grounds: (1) the platelet count generally is higher in arterial than in venous blood; (2) fewer platelets are found in the bone marrow than in the spleen or lungs; (3) perfusion of bone marrow yields few platelets whereas perfusion of the lungs produces many; (4) the megakaryocytes observed in the lungs appear to be actively producing platelets. They concluded that platelets are normally formed in the lungs from megakaryocytes which develop there in the same manner as in the bone marrow. Although the formation of megakaryocytes in the lungs has not been substantiated, there is considerable support for the claim that platelets are released in the lungs from megakaryocytes carried there in the venous blood from the bone marrow.<sup>221</sup> As many as 20 to 50% of the mature megakaryocytes may enter the blood, ultimately reaching the lungs, and 7 to 17% of the body's platelets may be produced there.

#### Blood

Megakaryocytes, or fragments of their nuclei or cytoplasm ("dwarf" megakaryocytes), are sometimes found in the circulating blood. These are of variable size and oval or irregular in shape. The nuclei stain deeply and may be surrounded by a small amount

of cytoplasm.<sup>146</sup> These fragments are rarely seen in routine peripheral blood smears, but are found regularly in the blood of normal individuals when concentration techniques are used.<sup>61,267</sup> Megakaryocyte fragments may be seen even in routine blood smears in various forms of cancer,<sup>191</sup> myelophthisic processes, chronic myelocytic leukemia, polycythemia vera, Hodgkin's disease, following surgical procedures, chest injury, and cardiac massage, and when there is leukocytosis due to infection.<sup>277</sup> They are seen less commonly in aleukemic leukemia, thrombocytopenic purpura, pernicious anemia, and plumbism.

## Kinetics of Thrombopoiesis

### Megakaryocyte Proliferation

Morphologically recognizable cells of the megakaryocyte line lack the capacity for self-

renewal, and are maintained by a continuous influx of precursor cells from the stem cell compartment. There is good evidence that an intermediate "multiplicative" pool of stem cells is "committed" to differentiate into megakaryocytes.<sup>116,119,391</sup> The maturation of these primitive cells into mature megakaryocytes involves a unique process<sup>204</sup> (Fig. 9-4).

*Maturation of the nucleus* involves nuclear endoreduplication (endomitosis), a process in which nuclear material reduplicates but the nucleus does not divide. This results in a polyploid nucleus as distinguished from a polyploid cell, such as the osteoclast. Each division produces a doubling of the total nuclear material. This eventuates in a series of cells containing the equivalent of 4, 8, 16, and 32 sets of chromosomes; this number also is referred to as the nuclear number (N), "ploidy" value, or class.

*Maturation of the cytoplasm*, manifested by

## MEGAKARYOCYTOPOIESIS

Fig. 9-4. Theoretical model of megakaryocytopoiesis. The earliest recognizable megakaryocyte is the  $8N$  cell. The wide arrows indicate the major pathway of nuclear and cytoplasmic maturation. The relative platelet yield per megakaryocyte is indicated by the + signs. (Based on the work of Odell et al.<sup>320,321,322</sup> From Hirsh and Doery<sup>177</sup> courtesy of the authors and *Progress in Hematology*.)

a progressive increase in its amount and granularity, and a loss of primitive basophilia, proceeds without cytoplasmic division. As judged by light microscopy, cytoplasmic maturation becomes apparent only after nuclear division has been completed. However, the development of cytoplasmic organelles is apparent much earlier in electron photomicrographs.<sup>338</sup> Both nuclear and cytoplasmic maturation result in an increase in the volume of the cell, ie, the largest megakaryocyte is the 32N granular (stage III) form. As estimated from DNA labeling in rats, the total megakaryocyte maturation time is approximately 60 hours<sup>118</sup>; in man an approximate figure of five days has been reported.<sup>92</sup>

Studies of the incorporation of <sup>3</sup>H-thymidine into the megakaryocytes of rats suggest that the primitive precursor is a 2N cell. Neither this cell nor the 4N cell is morphologically identifiable.<sup>118, 117, 119</sup> The mean nuclear number in the rat is 16N, but 8N and 32N cells are found in all stages of cytoplasmic maturation.<sup>327</sup> In man, 65% of the recognizable megakaryocytes in one study were of the 8N type as judged by microscopic nuclear counts.<sup>161</sup> With this method, a mean nuclear number of 8 was also found in the rat.<sup>158</sup> In view of evidence that DNA synthesis is confined to megakaryoblasts or even earlier precursors, it is probable that changes in nuclear lobulation associated with later maturation are unrelated to nuclear reduplication.<sup>321</sup> Nuclear lobe counts may be inaccurate as a means for the assessment of true ploidy value.<sup>118, 278</sup>

### Quantitation of Megakaryocytopoiesis

Since the platelet is produced by fragmentation of the cytoplasm of the megakaryocyte, the total number of platelets produced depends on the number and cytoplasmic volume of these precursor cells. Various methods for the enumeration of megakaryocytes have been described,<sup>344, 413</sup> none of which is entirely satisfactory. The one most widely used is an indirect method involving the microscopic determination of the number of megakaryocytes relative to the number of

erythroid precursors; the latter then are quantified with some degree of accuracy by labeling with radioactive iron. With this method, megakaryocytes normally number  $6.1 \pm 0.7 \times 10^6/\text{kg}$  body weight in man.<sup>156, 161</sup>

*Megakaryocyte volume* is difficult to determine accurately. Calculations based on surface area as measured in stained marrow smears<sup>156</sup> yield a mean figure of  $4200 \pm 100 \mu\text{l}$ .<sup>161</sup> For purposes of quantitation, an additional unit may be used, ie, the nuclear unit (the mean megakaryocyte volume divided by its nuclear number). This averages  $520 \mu\text{l}/\text{nucleus}$ .<sup>161</sup> The product of the total number of megakaryocytes and their mean volume is the *megakaryocyte mass*, which averages  $2.8 \pm 0.3 \times 10^{10} \mu\text{l}/\text{kg}$  body weight.<sup>161</sup>

When platelet production is stimulated, the megakaryocyte mass and total platelet production may increase as much as eightfold,<sup>159, 161</sup> as demonstrated by studies of patients with thrombocytopenia caused by accelerated platelet destruction. This results from a combination of accelerated nuclear reduplication, more rapid maturation, and, after an initial lag, increased input from the precursor compartment.<sup>160</sup>

### Platelet Distribution and Survival

#### Radioisotopic Techniques for Platelet Labeling

Among the isotopes presently available, <sup>51</sup>Cr-chromate and <sup>32</sup>P-diisopropyl-fluorophosphate are the most widely used for platelet labeling. The chromate ion binds to adenine nucleotides, and to various platelet proteins including thrombosthenin.<sup>400</sup> It is useful in man only as an in vitro whole population label. Low specific activity limits its usefulness in the study of thrombocytopenic subjects, although various technical modifications may obviate this difficulty.<sup>4</sup> DF<sup>32</sup>P is firmly bound by serine residues in platelet enzymes, is useful as either a cohort or total population label, and can be used both in vivo and in vitro.<sup>41</sup>

Neither DF<sup>32</sup>P nor <sup>51</sup>Cr-chromate are entirely satisfactory as platelet labels, how-

ever.<sup>172</sup> Both isotopes appear to label a predominantly young population of platelets<sup>213</sup>, both irreversibly damage or produce reversible sequestration of a small but possibly non-homogeneous population of cells<sup>41,172</sup>; and, in high concentrations, both compounds impair platelet function.<sup>219,297</sup> DF<sup>32</sup>P may prolong platelet survival,<sup>71</sup> and some <sup>32</sup>P released from effete platelets is recycled into circulating platelets.<sup>83</sup> Data suggesting that DF<sup>32</sup>P labels the megakaryocyte<sup>293</sup> have been disputed.<sup>83,121</sup>

Compounds such as <sup>75</sup>Se-selenomethionine<sup>301</sup> and <sup>35</sup>S-sulfate<sup>288</sup> are incorporated first into megakaryocytes and thence into circulating platelets, and consequently are useful as cohort labels in animals. <sup>75</sup>Se-selenomethionine is reincorporated into megakaryocytes, a significant disadvantage.<sup>301</sup> Because of rapid recycling of radioactivity, <sup>32</sup>P-phosphate<sup>152</sup> and <sup>14</sup>C-5-hydroxytryptamine<sup>170</sup> are no longer used as platelet labels.

EDTA is an unsuitable anticoagulant for *in vitro* platelet labeling since it markedly alters initial *in vivo* platelet distribution and recovery.<sup>16</sup> Most *in vitro* labeling techniques now employ acid-citrate-dextrose (ACD) additionally acidified to yield platelet-rich plasma of p<sub>H</sub> 6.5, a modification that minimizes platelet clumping.<sup>16</sup>

### Platelet Distribution *In Vivo*

When <sup>51</sup>Cr-chromate was used as an *in vitro* total population label, the initial *in vivo* recovery of labeled platelets averaged 65% in normal persons but was 90% or more in asplenic individuals.<sup>13,161</sup> Approximately two thirds of the total platelet mass thus appeared to be present in the circulation, while one third was in the spleen. This estimate has been confirmed by *in vitro* perfusion methods.<sup>312</sup> In the spleen, platelets apparently are sequestered within the sinuses or between the cells of the pulp. This splenic pool normally is interchangeable with the circulating platelet pool, and contains a disproportionately high percentage of young platelets.<sup>378</sup>

There are few data concerning the quanti-

tative significance of platelets produced by pulmonary megakaryocytes or of platelets present in the pulmonary vessels.<sup>221</sup> Judging by the rapidity with which thrombocytapheresis produces thrombocytopenia, platelet "reserves" in the lungs and other such extravascular sites appear to be minimal.<sup>38,87,258,377</sup> Platelets are not normally present in lymph or other body fluids.

### Life Span and Turnover Rate

Platelet life span, as estimated by *in vitro* whole population labeling with <sup>51</sup>Cr-chromate, ranges from 9 to 12 days in man.<sup>16,161</sup> Virtually identical values were obtained when DF<sup>32</sup>P was used as an *in vivo* whole population label.<sup>41,223</sup> Although the contour of the survival curves differed significantly, comparable figures for platelet lifespan also were obtained with <sup>75</sup>Se-selenomethionine and <sup>35</sup>S-sulfate.<sup>320</sup> Similar survival times were obtained with canine<sup>8</sup> and bovine<sup>279</sup> platelets, whereas platelet lifespan in rabbits,<sup>280</sup> mice,<sup>323</sup> and pigs<sup>354</sup> normally is shorter than in man.

In the steady state, platelet destruction is exactly balanced by platelet production, and an estimate of the number of platelets destroyed and replenished each day can thus be obtained by dividing the circulating platelet mass by the survival time in days. When appropriate corrections are made for variations in the initial recovery, a reasonably reproducible value for platelet turnover rate may be derived. This normally is  $35,000 \pm 4,300$  platelets/ $\mu$ l/day.<sup>161</sup>

### Fate of the Platelet

There is substantial clinical and experimental evidence that damaged or effete platelets are sequestered principally in the spleen<sup>13,11</sup> (Chapter 36). Vigorous controversy persists as to the major determinants of normal platelet survival and involves, for the most part, the interpretation of survival curves obtained with isotopically labeled platelets.<sup>11,96,293,298</sup> Rectilinear survival curves would be expected if the fate of the

platelet were determined mainly by senescence; curvilinear or first-order plots would be seen if the major factor were destruction by random processes unrelated to age.

In the majority of survival studies employing  $^{51}\text{Cr}$  as a total population label,<sup>16,161,238</sup> the plot was approximately rectilinear but deviated at the end, producing a "tail." Studies using  $\text{DF}^{32}\text{P}$  as an *in vivo* population label yield a similar linear plot, but in this case the "tail" presumably is due to recycling of the isotope.<sup>41,233</sup> When  $^{51}\text{Cr}$ -chromate was used as a cohort label in rats,<sup>143</sup> less than one third of the platelet loss appeared to be due to random destruction, a conclusion confirmed by recovery of the majority of the isotope from the reticuloendothelial system.<sup>14</sup>

On the other hand, survival curves obtained in animals with  $\text{DF}^{32}\text{P}$ -labeled platelets were curvilinear,<sup>121</sup> and the survival of cohorts labeled with  $^{35}\text{S}$ -sulfate and  $^{75}\text{Se}$ -selenomethionine appeared to be determined mainly by random loss. Similar results were obtained with platelets labeled with both  $^{35}\text{S}$  and  $\text{DF}^{32}\text{P}$ ,<sup>257</sup> a technique that provides a combined population and cohort label. The possibility remains that many of these discrepancies represent valid species differences.

The vast majority of available data suggests that platelet survival curves in man are neither truly rectilinear nor first-order,<sup>172</sup> and that both random destruction and senescence determine the fate of the platelet.<sup>172</sup> Many have concluded that senescence predominates under normal circumstances,<sup>16,83,288,332</sup> while others maintain that the major factor is random loss,<sup>96,116,305</sup> or favor more complicated models.<sup>286</sup> This question cannot be answered with available data and must await the development of new or improved labeling techniques.

### Ineffective Thrombopoiesis

A direct and linear relationship between platelet turnover rate, as measured by isotopic techniques discussed above, and the total megakaryocyte mass has been demonstrated in man<sup>161</sup> and in rats<sup>158</sup> (Fig. 9-5).

This relationship also holds true in a wide variety of disorders characterized by thrombocytopenia or by "reactive" thrombocytosis (Chapter 36). However, in thrombocytopenia associated with megaloblastic anemias (page 1097) and certain other disorders, this correlation is not seen (Fig. 9-5). The latter suggests that thrombopoiesis is "ineffective" in these disorders,<sup>161</sup> a phenomenon discussed in detail in Chapter 34.

### Regulatory Processes

The remarkable constancy of the platelet count under normal circumstances suggests that the production of these cells is well regulated, and the presence of humoral controlling factors analogous to erythropoietin (Chapter 4) has been postulated for many years.<sup>2,84</sup> Studies demonstrating the enhancement of platelet production by thrombocytapheresis and its depression by platelet transfusion provide good evidence for the presence of such a "thrombopoietin."<sup>326,377</sup> In animals, the effects of this humoral substance may be roughly quantified by measurements of the rate of RNA synthesis, and by determination of total platelet production rate by means of cohort labeling.<sup>126,159,340</sup> Several groups of workers have demonstrated stimulation of thrombopoiesis in animals given serum, plasma and fractions thereof, and urine derived from human and animal sources.<sup>223,238,324</sup> The results of such studies have not been entirely consistent,<sup>2</sup> and numerous nonspecific factors tend to confuse the results.<sup>324</sup> Newly developed assay systems may provide more adequate methods of studying "thrombopoietins."<sup>120,341</sup>

Attempts to isolate and chemically characterize thrombopoietic substances have met with only limited success. Preliminary studies suggest that an active principle migrates electrophoretically as an alpha-2 globulin, contains carbohydrate, is not dialyzable, and is thermostable.<sup>369</sup> In these respects it resembles erythropoietin, but it differs from this substance in terms of storage lability, its presence in nephrectomized animals,<sup>106</sup> and in several other respects.<sup>106,270,369</sup>

There is some evidence that a humoral thrombopoietic factor acts on the stem cell compartment.<sup>326</sup> Data obtained by means of the spleen-colonization technique in lethally irradiated mice (page 50) suggest that transplanted cells, possibly the megakaryocyte-committed stem cells, retain "thrombopoietic direction."<sup>122</sup>

Studies of cyclic variations in the platelet count in normal individuals,<sup>332</sup> and in patients with cyclic thrombocytopenia and tidal platelet dysgenesis (page 1098), suggest that the control of thrombopoiesis involves a negative "feedback" mechanism that contains a time delay. As a result of this time lag,

"perturbations" of either a positive or negative nature may be magnified, resulting in an oscillation of platelet production. More than one humoral regulator, or a combination of negative and positive "feedback" regulatory processes, may be involved.<sup>118,160,172,194</sup> Claims for the presence of thrombopoietic substances or inhibitors in the spleen<sup>82,310,404</sup> are not convincing.<sup>2,84,322</sup>

Clinical evidence for the presence of a humoral "thrombopoietin" is provided by a remarkable patient with a chronic, presumably congenital form of thrombocytopenia.<sup>369</sup> In this patient, who has been studied for over 15 years, the transfusion of normal plasma

Fig 9 5. Correlation between platelet turnover and megakaryocyte mass. The two measurements of platelet production were compared by plotting megakaryocyte mass against platelet turnover. The correlation indicates that these are equivalent measurements. The normal mean value  $\pm 1$  SD is represented by the black square located by the arrow. The confidence limits ( $\pm 1$  SD) are shown in the shaded area. In eight patients (open circles), marked disparity was seen between platelet turnover and megakaryocyte mass, a finding indicating significant ineffective thrombopoiesis (From Harker and Finch,<sup>161</sup> courtesy of the authors and the Journal of Clinical Investigation)

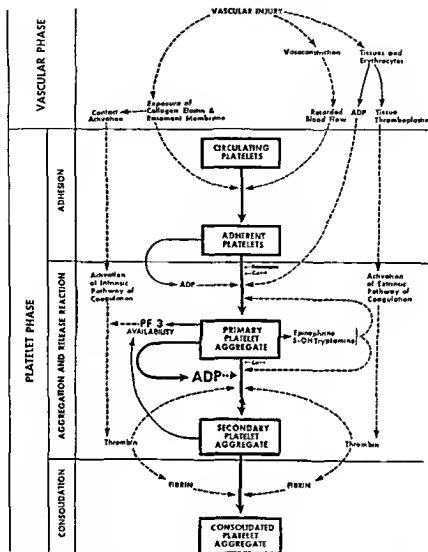

Fig 9-6 The vascular and platelet phases of hemostasis (primary hemostasis). Action is denoted by dashed lines, transformation including for purposes of illustration the release or activation of substances contained within the platelet, is illustrated by solid lines

(page 423) and platelet adhesion, discussed below, both of which are initiated by the exposure of collagen, and the initiation of the extrinsic pathway of coagulation by thromboplastins released from injured tissues (Chapter 10).

## The Platelet Phase of Hemostasis

In mammals, the major function of the platelet is hemostasis,<sup>53,244</sup> a process in which

this cell plays both a mechanical and a biochemical role. Hemostasis probably proceeds in the essentially stepwise manner indicated in Figure 9-6. Vascular injury results first in the adhesion of platelets to the vessel wall. Such adherent platelets release stored ADP (the release reaction). This initiates the formation of aggregates between platelets. The activation or "availability" of platelet factor 3 and the initiation of blood coagulation then follow, leading to the consolidation of the platelet plug by fibrin and subsequently to the phenomenon of clot retraction.

Platelet functions that are unrelated to hemostasis are discussed briefly on page 399. Numerous excellent reviews and monographs provide further details concerning platelet function.<sup>53,100,144,172,242,249,251,269,290,292,317</sup>

### Platelet Adhesion

The phenomenon of *platelet adhesion* (the attachment of platelets to non-platelet surfaces<sup>394</sup>) can be dissociated from *platelet aggregation* (the attachment of platelets to one another). In the presence of EDTA, a chelating agent that inhibits platelet aggregation, individual platelets adhere in a single layer to injured vessel segments without forming aggregates.<sup>393,395</sup> When ADP is infused into animals, platelet aggregates form in the blood stream but do not adhere to vascular surfaces.<sup>381</sup>

In experimental wounds, platelets appear to adhere mainly to exposed *collagen fibers* (Fig. 9-6).<sup>192,375</sup> This involves a specific biochemical interaction, which may be the formation of an enzyme-acceptor complex between incomplete heterosaccharide-lysine groups of collagen<sup>220a</sup> and glycosyl transferases in the platelet membrane.<sup>202</sup> Neuraminidase in the platelet membrane may expose acceptor groups for this enzyme by hydrolyzing terminal sialic acid residues in collagen.<sup>58</sup> This hypothesis is consistent with data demonstrating that the activity of collagen depends on its native fibrillar structure,<sup>168a</sup> intact galactosyl residues,<sup>262</sup> free sulfhydryl groups,<sup>10</sup> and the presence of epsilon amino groups of lysine,<sup>439</sup> but is unaffected by removal of the telopeptides or the blocking of free carboxyl groups.<sup>442</sup> The endothelial basement membrane also serves as a site of platelet adhesion,<sup>27,197,412</sup> and, since it contains acceptor groups similar to those of collagen, may interact with the platelet by means of a similar biochemical mechanism.<sup>202</sup> In large vessels which lack a basement membrane, platelets appear to adhere to *elastic fibers*.<sup>394</sup> Data concerning the role of the endothelial cell per se in platelet adhesion are contradictory.<sup>53,136,242,394</sup>

The adhesion of platelets to injured vascular surfaces also is conditioned by the ad-

sorbed protein coating of both the vessels and the platelets,<sup>362,394</sup> although the importance of specific plasma protein cofactors in this process has not been established. The ability of collagen to induce platelet aggregation is diminished as the result of interaction with certain normal plasma proteins.<sup>313</sup> Poorly understood rheologic factors also are probably of great importance in platelet adhesion, eg, the concentration of other cells in the perfusing blood, the rate of blood flow, the velocity gradient.<sup>26,93,167,234</sup>

Platelet adhesion to collagen and other biologic surfaces should not be confused with adhesion of platelets to glass or other foreign surfaces (page 1054). The latter may reflect quite different phenomena,<sup>362</sup> eg, the effects of the "anti VW factor" (page 1182), ADP-induced aggregation.

### Platelet Aggregation

Platelet aggregation follows adhesion of platelets to injured surfaces, and normally is apparent in experimental wounds within 15 seconds.<sup>192</sup> ADP is the central factor in this process (Fig. 9-6). Most evidence favors the view that ADP derived from injured tissues and erythrocytes<sup>339</sup> is of minor importance, and that, in a wound, aggregation is initiated mainly by ADP extruded from adherent platelets themselves during the release reaction.<sup>194,290</sup>

### Adenosine Diphosphate

Platelet aggregation induced by very low concentrations of ADP (0.1 to 0.4  $\mu\text{M}$ ) ("primary" aggregation) is reversible as regards both morphologic and biochemical changes.<sup>155</sup> At intermediate concentrations (0.4 to 1.5  $\mu\text{M}$ ) ("threshold concentrations"), aggregometer tracings reveal an initial "primary" wave of reversible aggregation followed by a second wave of irreversible aggregation that is produced by ADP released from the primary platelet aggregate ("secondary" aggregation) (Fig. 9-7).<sup>155,245</sup> With higher concentrations of ADP, the primary and secondary waves merge. In a minority of normal subjects biphasic aggregation does

## Miscellaneous Aggregating Agents

In vitro, platelet aggregation can be initiated by a variety of substances, all of which presumably act by inducing the release of ADP from the platelet. These include free fatty acids,<sup>163,177</sup> immunoglobulins<sup>101,343a</sup> and antigen-antibody complexes,<sup>283</sup> unconjugated bilirubin,<sup>260</sup> viruses<sup>206</sup> and bacterial toxins,<sup>189,205</sup> vasopressin,<sup>165</sup> snake venoms,<sup>101</sup> polymerizing fibrin monomers,<sup>390</sup> phytohemagglutinins,<sup>216a</sup> and even ultraviolet light.<sup>111</sup> Aggregation and the release reaction also may be initiated by many foreign particles and surfaces,<sup>89</sup> the effects of which are greatly modified by coating with various proteins.<sup>330</sup>

## The Platelet Release Reaction

A number of substances that are contained principally in the storage organelles and lysosomes of the platelet are extruded from the cell when it is physiologically stimulated.<sup>149,229</sup> This occurs rapidly,<sup>445</sup> involves the expenditure of considerable energy, and does not affect cytoplasmic or mitochondrial enzymes<sup>53</sup> or the integrity of the platelet membrane.<sup>179</sup> This phenomenon has been termed the platelet release reaction (Fig. 9-6), and is quite comparable to specific secretory functions of other cells.<sup>104,149,403</sup>

A remarkable diversity of biologically active substances are extruded from the platelet during the release reaction.<sup>172,307,455</sup> In addition to those already mentioned, these include calcium ions,<sup>415</sup> fibrinogen,<sup>149,222</sup> ATP, various vasoactive substances,<sup>303</sup> inorganic pyrophosphate,<sup>380a</sup> potassium ions,<sup>50,154</sup> various enzymes including acid phosphatase and beta glucuronidase,<sup>457</sup> platelet factor 4 (page 398),<sup>309,407</sup> and an "elastolytic" protease.<sup>453</sup> In view of the known biologic activity of many of these substances, it has been assumed that their release by the platelet has some physiologic significance, but there is little direct evidence for this hypothesis. There is some evidence that vasoactive substances released from the platelet may be of pathophysiologic importance in thromboembolic

disorders (Chapter 39) and in intravascular coagulation (Chapter 38). Permeability factors released from the platelet may have a physiologic role in inflammation<sup>294</sup> and possibly a pathologic role in inflammatory disorders such as rheumatoid arthritis.<sup>88</sup>

Large amounts of beta glycerol acid phosphatase are released into the plasma when platelets are damaged in vivo by various pathologic processes.<sup>332</sup> Measurements of plasma levels of this enzyme may provide a means of differentiating between thrombocytopenia caused by increased platelet destruction, and that resulting from deficient production (Chapter 34).

## The Role of ADP

ADP apparently is central to the hemostatic function of the release reaction. Owing to the exquisite sensitivity of the platelets to this nucleotide, even the small amounts of ADP released from adherent platelets are sufficient to induce aggregation of a much larger number. The resulting aggregate in turn releases ADP, leading to a still larger aggregate. It is thus difficult to delineate the phenomena of platelet adhesion, aggregation, and the release reaction with respect to time. At some point, the process becomes irreversible, a feature corresponding to the in vitro phenomenon of "secondary" aggregation discussed above.<sup>242</sup> The release reaction may be viewed as a "biologic amplifier" that rapidly converts a minimal stimulus into a massive hemostatically effective response.<sup>307</sup>

The ADP extruded during the release reaction originates in the storage nucleotide pool located within the platelet dense bodies. Approximately 50% of the storage ADP is released, this averaging 1.6  $\mu\text{M}/10^8$  platelets.<sup>455</sup> The energy required to operate the release mechanism is not derived from the storage pool, but rather from the breakdown of ATP from the metabolic nucleotide pool (Fig. 9-2).

The biochemical mechanism that initiates the release reaction is poorly understood. The substances extruded, as well as the concomitant "burst" of metabolic activity, vary

both qualitatively and quantitatively, depending on the agent that induces the release reaction.<sup>138,231,292,419,457,458</sup> The process is facilitated by calcium<sup>191</sup> but is not strictly dependent on this ion,<sup>389</sup> and may require a plasma cofactor distinct from plasma fibrinogen.<sup>90</sup> The release reaction induced by zymosan, inulin, and bacterial endotoxin depends on a preliminary interaction with the sixth component of complement (C' 6) in the plasma.<sup>382</sup> Under physiologic conditions, the major initiating factor may be close contact with "active" surfaces and other platelets.<sup>257</sup> The normally concurrent phenomena of aggregation and platelet factor 3 availability apparently are not essential for the release reaction, which appears to be a biochemically discrete event.

#### The Role of Cyclic AMP and Prostaglandins

The level of cyclic AMP (cAMP) in "resting" platelets is approximately 140 pM/10<sup>9</sup> platelets.<sup>365</sup> Despite active turnover, this low level is normally maintained within narrow limits by the action of two enzymes (Fig. 9-8), namely *adenyl cyclase*, which catalyzes the synthesis of cAMP from ATP,<sup>444</sup>

and *phosphodiesterase*, which degrades cAMP to AMP. Cyclic AMP inhibits ADP-induced platelet aggregation in vitro, but only in high concentrations,<sup>256</sup> a fact attributable to its rapid degradation by phosphodiesterase and its inability to penetrate the platelet membrane.<sup>348</sup> A congener, dibutyl cAMP, penetrates the cell rapidly, is not destroyed by phosphodiesterase, and is a potent inhibitor of platelet aggregation.<sup>256</sup>

*Inhibitors of platelet aggregation* increase the levels of cAMP in the platelet. Many of these act as inhibitors of phosphodiesterase, eg, various methyl xanthines,<sup>451</sup> papaverine, possibly adenosine and 2-chloroadenosine.<sup>185,273</sup> Prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) in low concentrations (1 μM) stimulates the action of adeny cyclase.<sup>444,451</sup> This substance inhibits both primary and secondary ADP-induced aggregation and the release reaction induced by thrombin, epinephrine, and other agents.<sup>224,374,445</sup> Other prostaglandins are active but are much less potent.<sup>227,451</sup>

Evidence concerning the relationship between cAMP and platelet aggregating agents is much less clear. Most substances that initiate platelet aggregation decrease platelet levels of cAMP. Epinephrine,<sup>267</sup> 5-HT, and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) may act as inhibi-

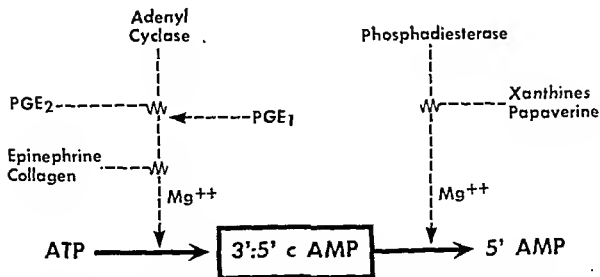

Fig 9-8 Agents that affect platelet levels of cyclic AMP. Dashed arrows indicate action, solid arrows indicate transformation.

tors of adenylyl cyclase<sup>274,415,451</sup>; collagen fibers and various foreign particles produce a similar effect.<sup>365</sup> Prostaglandins  $E_2$  and  $F_{2\alpha}$  apparently are synthesized in the platelet.<sup>388a</sup> They are released when the platelet is "stimulated," eg, by thrombin.<sup>37</sup> These data suggest that  $PGE_2$  may act as a physiologic counterbalance to the effects of  $PGE_1$ . ADP leads to a reduction in platelet cAMP levels, but has no effect on the activity of adenylyl cyclase or phosphodiesterase in cell homogenates.<sup>274,365</sup> Contradictory results have been obtained with thrombin. In some studies, this enzyme reduced cAMP levels and inhibited adenylyl cyclase<sup>365</sup>; in others, an increase in cAMP was observed.<sup>168</sup>

The data discussed above provide substantial evidence that cAMP and certain prostaglandins play an important role in mediating the responses of the platelet to various stimuli.<sup>227</sup> However, factors other than those involving adenylyl cyclase and phosphodiesterase may be of equal importance in regulating the levels of cAMP in the platelets.<sup>374</sup>

### Morphologic Changes

Most evidence would suggest that adhesion alone does not produce significant alterations in the form and structure of the platelets. The first definite change seen in vivo, or when ADP is added to platelets in vitro, is a rapid transformation of normally discoid platelets into spheres with numerous small protrusions or pseudopods ("spiny spheres").<sup>52,193</sup> This *initial shape change* is seen just before or at the same time as the release reaction. It occurs in the absence of calcium ions and thus is apparent even when aggregation is inhibited by EDTA or is lacking altogether, eg, in platelets from patients with thrombasthenia.<sup>460</sup> Electron photomicrographs reveal that the shape change is associated with a gathering together of various organelles in the center of the cell. This has been ascribed to the contraction of the marginal microtubules,<sup>429</sup> which may undergo a transformation into fibrils.<sup>65,428</sup> Data obtained by electronic particle counters which suggest that the initial shape change is accompanied by an increase in platelet volume<sup>65</sup> have been disputed.<sup>52</sup>

It has been suggested that the shape change may expose reactive groups on the platelet surface, or that the formation of pseudopods may act to stabilize platelet aggregates<sup>193</sup> and thus facilitate intimate adhesion of platelets to tissues and other cells.<sup>53</sup> There is no direct evidence for any of these hypotheses.

Chilling<sup>30,220,428</sup> and prolonged incubation with EDTA or cocaine<sup>65,364</sup> induce platelet "swelling." This phenomenon differs fundamentally from the shape change, and presumably is the result of the impairment of metabolic processes required to maintain a normal cell configuration; it may reflect reversible depolymerization of the microtubules.<sup>28,30,256,364</sup>

Platelets in aggregates formed in vitro by sub-threshold concentrations of ADP ("primary" aggregates) reveal only the shape change, a morphologic change that disappears as deaggregation occurs.<sup>155</sup> With higher concentrations of ADP ("secondary" aggregates), platelet pseudopods become longer, but individual platelets remain distinct and do not fuse.<sup>57,149,155,242</sup> However, slight shrinkage ("cohesion") of the aggregate may be seen. These morphologic changes are most marked in platelets in the superficial layers of the aggregate, and in those adherent to the endothelium,<sup>155,192</sup> and correspond to those commonly referred to by the term *viscous metamorphosis*. Many observers have reported platelet degranulation in secondary aggregates, but this finding has not been observed consistently.<sup>155,422</sup>

The structure of platelet plugs formed in vivo, although quite similar to the above, is more variable because of rheologic factors. The platelet plug adheres to adjacent morphologically normal endothelium,<sup>373</sup> and may either occlude or cap the end of the injured vessel. Although still permeable to some red cells, platelet plugs alone, without consolidating fibrin, may be hemostatically effective in small vessels.

### The Role of Platelets in Blood Coagulation

Various protein or lipoprotein substances derived from the platelet have come to be

designated as platelet "factors" because of their apparent function in blood coagulation. These are designated by Arabic numerals, in distinction to the Roman numerals used in referring to the coagulation factors (Table 10-1, page 410).

### Platelet Factor 3

Platelet factor 3 (PF-3) is required in at least two steps in the process of blood coagulation, namely, the interaction between factors IXa and VIII which results in the activation of factor X (Fig. 10-4, *reaction 4*, page 424), and the interaction between factor Xa and factor V which leads to the formation of prothrombinase (*reaction 7*). Platelet factor 3, or a substitute phospholipid, also is required for the activation of factor X by the venom of Russell's viper (*Stypven*) (*reaction 14*). Details of these reactions are discussed in the following chapter.

Platelet factor 3 is a thermostable lipoprotein. When isolated from platelet homogenates, it is found mainly in the particulate fractions that contain platelet membranes and granules<sup>292</sup>; it also is found in platelet "dust."<sup>443</sup> When "activated" by ADP and other substances under various *in vitro* conditions, PF-3 remains closely associated with the platelet membrane.<sup>154,172,188</sup>

Non-sedimentable material with PF-3 activity can be demonstrated in serum,<sup>315</sup> and following protracted incubation of platelets with thrombin.<sup>101,187</sup> The significance of such "soluble" PF-3 is difficult to assess, since assays for PF-3 activity are quite non-specific. Phospholipids which substitute for platelets in all of the various assay methods can be extracted from most tissues, including erythrocytes.<sup>75</sup> Indeed, a variety of substances ranging from crude fractions of cephalin or soybean phosphatides to purified phosphatides exhibit a comparable activity. None of these PF-3 "substitutes" is as potent as isolated platelet membranes.<sup>252</sup> It has been suggested that "soluble" PF-3 plays no physiologic role under normal circumstances and represents solubilized membrane lipoprotein or phospholipids which passively leak from dead cells.<sup>172,219</sup> It is for this reason that

PF-3 activity which is demonstrated in frozen or sonicated whole platelet suspensions, although often assumed to represent a quantitative measure of "total PF-3," has little specific significance.

The evidence cited above would suggest that PF-3 is in reality the platelet membrane which, when suitably "activated" or "made available," acquires the ability to bind and orient activated coagulation factors. The complex so formed acquires enzymatic properties, i.e., the ability to activate either factor X or prothrombin.

The precise interrelationships between platelet aggregation, the release reaction, and PF-3 availability remain uncertain.<sup>419</sup> The three phenomena normally are closely related, and the amount of PF-3 made available during ADP-induced aggregation is roughly proportional to the extent and duration of aggregation.<sup>154,385</sup> There is, however, evidence that neither ADP nor the release reaction is essential.<sup>18,138,317</sup> Platelet factor 3 becomes available after the release of ADP and 5-HT<sup>385</sup> and before thrombin formation or visible alterations in the platelet membrane are apparent<sup>219</sup>; under some experimental circumstances it may even be a reversible phenomenon.<sup>317</sup> Most data favor the hypothesis that PF-3 availability, like the release reaction, is initiated as the result of close apposition of the platelet to "active" surfaces,<sup>392</sup> including other platelets.<sup>138</sup>

Under certain *in vitro* conditions, platelets acquire an activity similar to that of a complete tissue thromboplastin; i.e., they are capable of activating factor VII and the extrinsic pathway of coagulation<sup>10</sup> (Chapter 10). This phenomenon appears to depend on contact activation and factor XII. There is indirect evidence that platelets also may initiate the process of contact activation.<sup>70,424</sup> Studies suggesting that this is mediated by ADP released from the platelets require confirmation.<sup>315</sup> None of these reactions is of established physiologic significance.

### Other Platelet Factors

*Platelet factor 2* (PF-2) (fibrinogen activating factor) is a globulin of indeterminate

molecular weight. When semipurified fractions of this substance are incubated with fibrinogen, nonprotein nitrogen is released, suggesting a proteolytic action. In vitro, PF-2 inhibits antithrombin III, induces platelet aggregation, and accelerates the rate of the thrombin-fibrinogen reaction.<sup>127,308</sup>

*Platelet factor 4* (PF-4) (antiheparin factor) is a small glycoprotein or large glycopeptide of great thermostability and unusual resistance to proteolysis. This substance is extruded together with ADP during the release reaction,<sup>306</sup> although under certain in vitro conditions its activity remains localized to the platelet membrane.<sup>317,318</sup> In vitro, PF-4 facilitates ADP-induced aggregation under certain circumstances,<sup>241</sup> and antagonizes the anticoagulant effects of heparin and those of certain fibrinogen degradation products (page 436). It precipitates soluble fibrin monomers, and in high concentrations may also precipitate fibrinogen.<sup>241,309</sup> These properties may play a role in the pathophysiology of intravascular coagulation and in various "paracoagulation" phenomena (page 1217).<sup>241</sup>

The term "platelet factor 1" refers to adsorbed plasma coagulation factor V<sup>176</sup> and platelet factor 5 refers to platelet fibrinogen (page 378). A plasmin inhibitor associated with the platelets is sometimes termed "platelet factor 6."<sup>124</sup> The nature and physiologic importance of platelet factor 7 ("co-thromboplastin"), PF-8 (antithromboplastin), and PF-9 (accelerator globulin stabilizing factor) are obscure. These terms, and platelet factor 10 (5-hydroxytryptamine), are rarely used.

### The Consolidation Phase

Fibrin acts to reinforce the primary or temporary platelet thrombus,<sup>374a</sup> and usually is apparent in experimental hemostatic plugs within one minute or even earlier. Fibrin strands are first seen on the surface and in the inner layers of the thrombus, particularly in association with those platelets that are adherent to the endothelium.<sup>8,192</sup> Fibrin often

is absent among the intervening layers of platelets.<sup>221,375</sup> In the presence of continued blood flow, fibrin is deposited as a cap over the entire thrombus and adjacent normal endothelium. The end result of these events, which are arbitrarily termed the "consolidation phase," is the permanent hemostatic plug that has become impermeable, more dense, mechanically stronger, and slightly diminished in volume.<sup>194</sup>

In common with the formation of the primary platelet thrombus, the events of the consolidation phase vary depending on rheologic factors.<sup>375</sup>

### Clot Retraction

There is little evidence in support of older theories that attributed the phenomenon of clot retraction to nonspecific syneresis of fibrin or mechanisms extrinsic to the platelet acting directly on fibrin.<sup>39</sup> In whole blood, clot retraction usually is slow and is deficient if the platelet count is below  $50 \times 10^9/\mu\text{l}$ . In platelet-rich plasma, retraction is more rapid, and in extent is directly proportional to the platelet count, if it is less than  $100 \times 10^9/\mu\text{l}$ , and is inversely proportional to the fibrinogen concentration.<sup>39,64</sup>

Clot retraction apparently begins when platelet clumps adhere to fibrin strands. This occurs at an undefinable point in the consolidation phase, and in a relatively specific manner; ie, the platelets adhere at the point where fibrin strands cross one another ("nodes"), and their pseudopods attach to the radiating fibrin strands.<sup>32,192</sup> This is thought to produce a three-dimensional lattice<sup>409</sup> such that, when the pseudopods shorten, contraction of the entire mass occurs. In platelet-rich plasma, this may produce a reduction of as much as 90% in the volume of the clot.<sup>39</sup> The adhesion of platelets to fibrin is an essential preliminary to clot retraction, but the process is poorly understood. There is some evidence that it is mediated by the interaction of platelet fibrinogen with fibrin strands of plasma origin,<sup>125,436</sup> and that it may involve PF-4.<sup>309</sup> Stabilized fibrin is less readily retracted than is non-stabilized fibrin.<sup>311</sup>

The mechanical work of clot retraction is carried out by thrombosthenin (page 379),<sup>34,302</sup> acting as a  $Mg^{++}/Ca^{++}$ -dependent adenosine triphosphatase.<sup>302</sup> Glucose is utilized and ATP is synthesized throughout the entire process. The complete abolition of clot retraction by metabolic inhibitors requires inhibition of both glycolytic and oxidative pathways; either pathway alone is able to provide sufficient energy for the process.<sup>112,284</sup> Thrombin and calcium ions also are required for clot retraction.

Clots formed by the enzyme reptilase do not retract.<sup>282</sup> It is uncertain whether this is due to a specific effect of this enzyme on the platelet<sup>310</sup> or the fact that reptilase removes only fibrinopeptide B from fibrinogen (page 412).<sup>282</sup>

The *homeostatic significance* of clot retraction has been debated extensively and remains unsettled. The phenomenon has been likened to a physiologic "ligature"<sup>134,135</sup> that progressively pulls the sides of an injured vessel together. The extensive studies of Budtz-Olsen<sup>64</sup> would suggest, to the contrary, that the mechanical force of clot retraction, estimated to be less than 20 mm of water in whole blood, is too feeble to produce such an effect. Budtz-Olsen suggested that clot retraction is a vestigial hemostatic function. Clot retraction may, however, exert a significant mechanical force in hemostatic plugs composed mainly of platelets, in contrast to whole blood clots, where the process is impeded by trapped erythrocytes.<sup>39</sup>

## Homeostatic Control Mechanisms

Several processes that could act to limit the intravascular propagation of the platelet thrombus have been demonstrated *in vitro*, but their homeostatic importance is uncertain.<sup>172</sup> Thus, the plasma contains adenylyl kinase, an enzyme that rapidly breaks down free ADP.<sup>182</sup> Electron microscopic studies would suggest that the superficial layers of the primary hemostatic plug are composed of reversibly aggregated or "refractory" platelets,<sup>360</sup> which may deaggregate and be

washed away. Evidence that ATP, adenosine formed in the plasma from ATP,<sup>360</sup> and serotonin<sup>24</sup> inhibit ADP suggests that the release of these substances in high concentrations may constitute a physiologic inhibitor of further platelet aggregation.<sup>25</sup> There is preliminary evidence that platelet deaggregation is specifically induced by stimulation of beta adrenergic receptors on the platelet,<sup>1a,63</sup> a phenomenon that may be mediated by cAMP. When consolidation of the primary hemostatic plug occurs, the platelet aggregate presumably is excluded from the circulation by a fibrin barrier, which may limit the size of the platelet thrombus.

## Miscellaneous Platelet Functions

Various properties of the platelet that are not concerned primarily with hemostasis will be discussed in this section. The evidence for the physiologic importance of these "functions" is incomplete, and various reviews of these specialized topics should be consulted for more details.<sup>283,201,292,294,298</sup> The role of platelets in fibrinolysis is discussed in Chapter 10.

### Endothelial Support

A long-standing hypothesis holds that *platelets act to maintain or support the integrity of the vasculature by attaching to gaps which normally develop in the endothelium, or as the result of their actual entrance and incorporation into endothelial cells.*<sup>208,209,417,441</sup> When isotopically labeled platelets are infused into thrombocytopenic animals, radioactivity may be subsequently demonstrated in the endothelium.<sup>91,411</sup> However, this phenomenon could not be demonstrated in normal animals.<sup>92</sup> Certain electron photomicrographs have been interpreted as showing the actual incorporation of platelets into endothelial cells,<sup>208</sup> but numerous ultrastructural studies of a similar nature have failed to reveal this phenomenon. The results of such studies are difficult to evaluate in any case,<sup>251</sup> and there is a large body of data

suggesting that platelets do not adhere to entirely normal endothelium.<sup>175,251</sup> Radiation-induced thrombocytopenia results in the rapid appearance of erythrocytes in the lymph of dogs,<sup>417,446</sup> but neither vascular fragility nor uncomplicated thrombocytopenia in man is necessarily associated with increased vascular permeability, as measured by the loss of <sup>131</sup>I-labeled albumin.<sup>421</sup> In vitro perfusion of the thyroid with platelet-rich plasma prevents degenerative changes that develop in the endothelium when platelet-poor plasma is used.<sup>142</sup> This effect could not be confirmed with perfused kidneys.<sup>427</sup> Finally, studies of platelet survival and sequestration in man, as discussed on page 386, would suggest that only a small proportion of platelets is consumed by random processes under normal circumstances; this is not significantly increased in patients with protracted thrombocytopenia caused by deficient platelet production.<sup>161</sup>

The available evidence favors the conclusion that platelets are utilized to *repair* small or imperceptible vascular injuries rather than to *support* or *maintain* normal endothelium.

## Phagocytosis

There is evidence that platelets, by means of a process similar to phagocytosis, engulf various foreign particles, eg, Thorotrast, India ink, carbon, polystyrene, and some bacteria.<sup>130,291</sup> It is often difficult to differentiate between true phagocytosis and passive attachment of particles to the membrane which lines the surface connecting canalicular system<sup>86,432</sup> or entrapment of particulate matter in the canalicular system during fixation. For example, myxoviruses are attached to the platelet surface coat, including that which lines the canalicular system, by means of specific glycoprotein receptors.<sup>206</sup>

The physiologic significance of platelet "phagocytosis" is obscure. It plays no apparent role in defense against infection, but may provide an ancillary, possibly vestigial mechanism for clearing particulate material from the blood.<sup>416</sup>

## Transport Functions

The platelet concentrates various substances by means of active metabolic processes. These active "transport" functions should be distinguished from passive adsorption;<sup>172,209</sup> which was discussed earlier (page 378). The platelets contain virtually all of the blood 5-hydroxytryptamine (5-HT), which is concentrated by means of a complicated biochemical process. Epinephrine<sup>56,57</sup> and potassium also are concentrated by means of active processes,<sup>81</sup> the latter presumably involving the same membrane receptor as 5-HT.<sup>24</sup> The release of potassium from platelets during coagulation is a common cause of "pseudohyperkalemia" (page 1106).

The assumption that the active and specific transport of such biologically potent substances by the platelet serves a purpose would seem reasonable, but supporting evidence is scanty. Abnormalities in platelet transport of 5-HT have been demonstrated in multiple sclerosis,<sup>68</sup> Down's syndrome,<sup>59</sup> and in certain other disorders.<sup>63</sup>

of a visible coagulum, which is the physical manifestation of fibrin formation, represents only the end result of an intricate series of reactions that involve a number of factors. Despite rapid advances in the past 30 years, many aspects of the process of blood coagulation still are poorly understood, and this field remains one of the major "frontiers" of hematologic research.

For more detailed information than can be included in the following summation, the reader is referred to the many excellent books, monographs, and reviews concerned generally with this topic,<sup>59,62,145,225,365,381,450</sup> and to those that deal with its various special aspects, eg, immunology,<sup>110</sup> kinetics,<sup>59,140,195,196</sup> comparative physiology.<sup>5,120,191,302,305</sup> Much information concerning normal coagulation has been obtained from the study of patients and animals with hereditary deficiencies of the various coagulation factors; this is summarized in Chapter 37. Assays for the various coagulation factors are discussed in Chapters 33 and 37. The role of coagulation factors associated with platelets was discussed in Chapter 9.

### The Blood Coagulation Factors

#### Nomenclature

The nomenclature of the coagulation factors has been notoriously inconsistent and

**B**LOOD coagulation was one of the first biologic processes to be studied experimentally, and many workers better known for their contributions to other disciplines were intrigued by the phenomenon, including Hunter, Lister, Virchow, Arthus, and Bordet.<sup>304</sup> The apparent simplicity of coagulation proved to be deceptive. The formation

confusing. Substances involved in this process which were defined prior to the present century received descriptive names, eg, fibrinogen, thrombin, prothrombin, thromboplastin. As information accumulated, new factors were named according to elementary biochemical or functional properties, eg, "labile" factor, "serum prothrombin conversion accelerator." More recently, they have received the surnames of the kindreds in whom hereditary deficiencies of the factors were first discovered, eg, Christmas, Stuart, Hageman. In the resulting confusion, several different terms for the same substance often were in simultaneous use.

These problems have been partially solved by the development of an international standard nomenclature.<sup>5,13</sup> Each coagulation factor is designated by a Roman numeral (Table 10-1). The term "factor VI," which originally referred to the activated form of factor V, has been abandoned. The descriptive terms "fibrinogen," "prothrombin," "calcium," and "tissue factor" will be used

here in preference to the Roman numerals indicated in Table 10-1.

The international nomenclature clearly distinguishes between the coagulation factors and the numbered factors related to the platelets; the latter are designated with Arabic numerals (page 397). It also can be adapted to a "shorthand" representation of coagulation reactions. By convention, activated forms of factors are designated by adding "a." For example, the conversion of factor X into its active form is written:  $X \rightarrow X_a$ .

### General Properties

Some elementary properties of the coagulation factors are summarized in Table 10-2. It should be emphasized that much of the basic information concerning these proteins is of limited accuracy. With the exception of fibrinogen and prothrombin, the coagulation factors are trace proteins, and in most instances information concerning their biochemistry (column 2) has been obtained from

Table 10-1. Nomenclature and Synonyms for Coagulation Factors

Roman Numeral	Preferred Descriptive Name	Synonyms
✓ I	Fibrinogen	
✓ II	Prothrombin	
✓ III	Tissue factor	Thromboplastin
✓ IV	Calcium ions	
I V	Proaccelerin	Labile factor, accelerator globulin (AcG), thrombogen
✓ VII	Proconvertin	Stable factor, serum prothrombin conversion accelerator (SPCA), autoprothrombin I, cothromboplastin
✓ VIII	Antihemophilic factor (AHF)	Antihemophilic globulin (AHG), antihemophilic factor A, platelet cofactor 1, thromboplastinogen
✓ IX	Plasma thromboplastin component (PTC)	Christmas factor, antihemophilic factor B, autoprothrombin II, platelet cofactor 2
X	Stuart factor	Prower factor, autoprothrombin III, thrombokinase
XI	Plasma thromboplastin antecedent (PTA)	Antihemophilic factor C
XII	Hageman factor	Glass factor, contact factor
XIII	Fibrin stabilizing factor (FSF)	Laki-Lorand factor (LLF), fibrinase, plasma transglutaminase

Table 10-2. Some Properties of the Coagulation Factors

Factor (1)	Biochemistry (2)	Biosynthesis (3)	Biologic Half-life* (Hours) (4)	Activity in		Function (7)
				Serum (5)	Adsorbed Plasma (6)	
Fibrinogen	Rod shaped glycoprotein, MW 340 000 three globular subunits	Hepatic	72-120	Absent	Unchanged	Precursor of fibrin, common pathway
Prothrombin	Monomeric glycoprotein, MW 69,000, $\alpha$ -2 or $\beta$ Globulin	Hepatic, vitamin K-dependent	72	Absent	Absent	Proenzyme, precursor of thrombin, common pathway
Factor V	MW > 200 000, $\beta$ lipoprotein	Hepatic	?	Absent	Unchanged	Common pathway
Factor VII	$\alpha$ or $\beta$ Globulin, glycoprotein MW ~48-100,000	Hepatic, vitamin K-dependent	12-36 4-6	Absent Increased	Absent	?Proenzyme, extrinsic pathway
Factor VIII	$\alpha$ 2 or $\beta$ Globulin MW > 2,000 000 $\beta$ lipoprotein	?Hepatic TRE system	10-14	Absent	Unchanged	Intrinsic pathway
Factor IX	$\alpha$ or $\beta$ Globulin glycoprotein MW ~50-200 000	Hepatic vitamin K-dependent	24	Increased	Absent	?Proenzyme, intrinsic pathway
Factor X	$\alpha$ Globulin or prealbumin MW ~50-100,000, glycoprotein	Hepatic, vitamin K-dependent	72-60	Unchanged	Absent	Proenzyme, common pathway
Factor XI	$\beta$ or $\gamma$ Globulin, MW ~50-200 000	?Hepatic	746-84	Unchanged	Slightly decreased†	Proenzyme, intrinsic pathway
Factor XII	$\beta$ or $\gamma$ Globulin, MW ~80,000	?	52-60	Unchanged	Unchanged	Proenzyme intrinsic pathway
Factor XIII	$\alpha$ 2-Globulin, MW 320,000, 4 molecular subunits	?Hepatic	72-120	Decreased	Unchanged	Proenzyme; transglutaminase, common pathway

\*Biologic half life, as distinguished from overall in vivo half life or half disappearance time

†Variable, depending on concentration of adsorbent

Question marks indicate insufficient data or significant disagreement between published figures

the study of relatively impure preparations. Most of the information concerning the *in vivo* production, distribution, metabolism, and catabolism of these proteins, i.e., their biodynamics (columns 3 and 4), has been derived from rather inaccurate experiments in patients with hereditary deficiencies of the various factors. Certain biodynamic properties of the coagulation factors are discussed in Chapter 37.

Certain properties of the coagulation factors are included in Table 10-2 primarily because they provide the basis for various *in vitro* tests of coagulation (Chapters 33 and 37), e.g., the presence or absence of the various factors in serum (column 5), their differential absorption by aluminum hydroxide and similar inorganic gels (column 6).

The process of coagulation may be divided into three essentially separate pathways, as described on page 422 (Fig. 10-3). The particular pathway in which the coagulation factors act and the presumed function of each are summarized in Table 10-2, column 7. In the following section, the biochemical and biodynamic properties of the individual factors will be summarized. Details of the interactions between these factors and the properties of their activated forms are discussed in a later section (page 421).

### Fibrinogen

Fibrinogen is a plasma protein that is converted into fibrin in the common pathway of coagulation. Fibrin constitutes the physical basis of all blood clots, and provides the framework for the permanent hemostatic plug (page 398). Fibrinogen also may be essential for normal platelet function (page 392) and wound healing (page 440).

### Biochemistry

Fibrinogen is a relatively insoluble glycoprotein that contains from 3 to 5% carbohydrate.<sup>69,272-414</sup> Purified preparations that are homogeneous by most criteria have been obtained by a number of relatively simple biochemical methods.<sup>70-92,203-268</sup> Such purified fibrinogen is 95 to 97% coagulable by throm-

bin, a figure that approximates the theoretic maximum because 3 to 5% of the molecule is lost as fibrinopeptides during coagulation.<sup>77</sup> The molecular weight of highly purified human fibrinogen is approximately 340,000.<sup>72,92</sup>

Electron microscopy has revealed that the fibrinogen molecule is composed of three nodular subunits, 5 to 7 nm in diameter, interconnected by a thin filament about 1.5 nm thick.<sup>183</sup> Studies of molecular subunits, obtained by dissociating the native protein in reagents such as sodium sulfite<sup>202</sup> or cyanogen bromide<sup>78</sup> suggest that fibrinogen has a dimeric structure (Fig. 10-1).<sup>2,12,74</sup> Each half of the molecule contains three identical pairs of polypeptide chains (designated alpha, beta, and gamma), which have respective molecular weights of 73,000, 60,000, and 50,000.<sup>327</sup> The two halves of the molecule are connected by three *intradimer* disulfide bonds, and the three chains comprising each half are firmly interconnected by *interchain* disulfide bonds, which are concentrated in the N-terminal end of the molecule (*the N-terminal disulfide knots*). These disulfide knots appear to be in the central portion of the molecule,<sup>2</sup> rather than in the lateral nodules as previously supposed.<sup>78</sup> Three pairs of terminal amino acid residues are present.<sup>78</sup> In human fibrinogen, these residues are alanine or asparagiosic (alpha chain), pyroglutamic acid (beta chain), and tyrosine (gamma chain).<sup>73,77</sup>

Two pairs of peptides are removed proteolytically from the fibrinogen molecule by the action of thrombin (Fig. 10-5, II). These have been designated *fibrinopeptides A and B*, and correspond to the terminal ends of the alpha and beta chains (Fig. 10-1). The terminal peptides of the gamma chains are not removed by the action of thrombin. Fibrinopeptide B is chemically homogeneous, but two subtypes of peptide A have been isolated (fibrinopeptides AY and AP).<sup>71,77</sup> Fibrinopeptide B normally is removed by thrombin more slowly than is fibrinopeptide A<sup>74</sup>; the removal of fibrinopeptide B is not required for coagulation.<sup>224</sup>

The venoms of some snakes, including *B. jararaca* (Reptilase) and *A. rhodostoma* (Arvin), contain enzymes that selectively re-

Fig 10-1. The molecular structure of the fibrinogen molecule. The two halves of the fibrinogen molecule (separated by the dotted line) and the constituent three pairs of chains are indicated (diagonal hatched lines = alpha chain, gray = beta chain, white = gamma chain). Stable disulfide bonds between the dimers and between the chains are indicated by solid black lines. Labile disulfides are not illustrated. Also indicated are the two peptides (A, B) cleaved by thrombin (arrows) and the site of the amino acid substitution which is present in fibrinogen *Detroit* (?) (page 1175). Note that the disulfide knots are disproportionately large in the diagram, they comprise only 1.6% of the molecule. (Diagram modified from Wallen<sup>225</sup> and Blombäck<sup>72,73</sup>)

move peptide A.<sup>142,221</sup> The active enzyme in the venom of the southern copperhead (*A. contortrix*) removes fibrinopeptide B more rapidly than fibrinopeptide A.<sup>209</sup>

Peptide sequences of the fibrinopeptides<sup>77</sup> and of larger subunits of the molecule<sup>74,78</sup> have now been determined. Detailed studies of fibrinogens of animal origin have revealed minor but consistent differences from the human protein.<sup>72</sup>

### Biodynamics

Fibrinogen is synthesized by the parenchymal cells of the liver.<sup>156,212,332,492</sup> Approximately 75% of the total body pool of

this abundant protein is present in the plasma,<sup>23,297,500</sup> where the concentration normally ranges from 160 to 415 mg/dl (page 1060). Fibrinogen is present in lesser amounts in lymph,<sup>80,96,194</sup> and may enter the circulation via the hepatic lymphatics.<sup>12</sup> It can be demonstrated in many tissues by immunofluorescent techniques.<sup>166</sup> Infused fibrinogen equilibrates slowly with these extravascular pools.

Extensive studies employing isotopically labeled fibrinogen have revealed that the kinetics of its catabolism are very complicated.<sup>12,34,106,297</sup> The turnover rate of human fibrinogen ranges from 1.7 to 5.0 g/day (30 to 60 mg/kg/day)<sup>25,297,500</sup> As determined in

patients with hereditary afibrinogenemia, the biologic half-life ranges from three to five days.<sup>100,429,544</sup> There is indirect evidence that catabolism occurs continuously<sup>34,500</sup> and may involve the conversion of fibrinogen into soluble derivatives of lower molecular weight; these have been isolated from normal plasma (fraction I-8).<sup>188,342,463</sup> The *in vivo* sites of fibrinogen catabolism are unknown.

The maximal production rate of fibrinogen may increase greatly under experimental conditions.<sup>261</sup> There is indirect evidence that plasma levels of fibrinogen degradation products, possibly acting as a "feed back" control, may constitute the major regulators of the rate of fibrinogen synthesis.<sup>261</sup> In tissue culture, free fatty acids increase fibrinogen synthesis by human liver slices.<sup>353</sup>

### The Vitamin K-Dependent Coagulation Factors

#### Vitamin K

Studies by several groups culminated almost simultaneously in the 1930's in the identification of vitamin K, the recognition of its importance as an "anti-bleeding factor" in obstructive jaundice, and the development of a specific pharmacologic antagonist of its action. To a large extent, subsequent studies have only amplified these remarkable pioneering endeavors.<sup>99,514</sup>

#### Pharmacology

In nature, vitamin K exists in two forms (Fig. 38-1, page 1203), i.e., vitamin K<sub>1</sub> (phytylquinone), which is found in various vegetable oils and leafy plants, and the vitamins K<sub>2</sub> (menaquinones), a group of closely related compounds that are synthesized by various bacteria, including common gut flora. It has been difficult to establish dietary requirements for this vitamin.<sup>158</sup> There is evidence in both animals and man that the vitamin K formed in the colon, where most is synthesized, is not absorbed, and the importance of dietary sources of this vitamin may be greater than previously realized.<sup>512</sup>

Both vitamin K<sub>1</sub> and the vitamins K<sub>2</sub> are fat soluble, and as a consequence are absorbed only in the presence of bile salts. They are carried in the plasma bound to albumin. No significant body stores of either form of vitamin K have been demonstrated.<sup>99</sup>

The coumarin-like drugs inhibit the physiologic action of vitamin K, and are discussed in detail on page 1243.

#### Function

Vitamin K is required for the biosynthesis of four coagulation factors: prothrombin and factors VII, IX, and X. Reports that factor XI also is vitamin K-dependent have not been confirmed.<sup>415</sup> The essential role of vitamin K in the synthesis by the hepatic cell of these coagulation factors has been demonstrated directly in liver cell homogenates, slices, and isolated microsomes,<sup>42,245</sup> as well as by means of extracorporeal perfusion of the intact liver.<sup>121,380,405,410</sup> In the case of factor IX, the results of liver perfusion have been equivocal.<sup>380,405</sup>

The biochemical mode of action of the vitamins K remains obscure. These vitamins are not incorporated into any circulating coagulation factor, and data pertaining to the effects of vitamin K on mitochondrial electron transport and oxidative phosphorylation in bacteria are of uncertain significance in man.<sup>99</sup> Evidence obtained from the study of the inhibitory effects of coumarins, and non-specific inhibitors of protein synthesis such as actinomycin and puromycin,<sup>36,211</sup> suggests that the vitamins K catalyze the last of at least two synthetic steps leading to the production of the various coagulation factors (Fig. 10-2). Consistent with this view is evidence that coumarin drugs and vitamin K deficiency induce the formation of abnormal molecular analogs of the vitamin K-dependent coagulation factors. These may represent a common precursor, or "incomplete" individual coagulation factors. Detailed biochemical studies of "dicoumarol-induced" prothrombin of cows<sup>348,487,488</sup> have demonstrated that this totally nonfunctional protein is identical to normal prothrombin with respect to its elec-

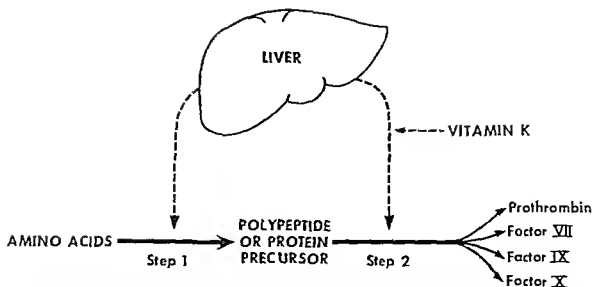

Fig. 10-2. Two-step hypothesis for biosynthesis of vitamin K-dependent coagulation factors. A solid arrow denotes transformation, a dashed arrow denotes action. When step two is inhibited as a result of deficiency or inhibition of vitamin K, the precursors produced in step 1 accumulate. This would be marked if the "feedback" that regulates the synthetic rate acts primarily on step 1.<sup>35,196</sup>

trophoretic mobility, amino acid composition, and major antigenic determinants, but lacks  $\text{Ca}^{++}$  binding sites. These data are consistent with the hypothesis that the second, vitamin K-dependent biosynthetic step (Fig. 10-2) involves the formation of  $\text{Ca}^{++}$  binding sites on the prothrombin molecule. Contrary to earlier hypotheses,<sup>35,196</sup> this step does not appear to involve the attachment of a sugar or glycoprotein moiety.<sup>316,487,488</sup> Other substances that may be related to "dicoumarol-induced" prothrombin include the "protein induced by vitamin K absence or antagonism (PIVKA)," a functionally inert protein that is a competitive inhibitor of factor X,<sup>196</sup> and "pre-prothrombin," a substance that resembles prothrombin biochemically, but is activated *in vitro* only by staphylocoagulase.<sup>199,248,478</sup> Qualitatively abnormal forms of factors VII, IX, and X also have been demonstrated by immunologic methods.<sup>111</sup>

### Prothrombin

Prothrombin is a proenzyme, the precursor of thrombin, that functions in the common pathway of coagulation.

Highly purified prothrombin has been prepared from both human and bovine plasma.<sup>27,236,308,309,504</sup> Human prothrombin has a molecular weight of 69,000 and contains from 2 to 10% carbohydrate.<sup>248,274</sup> It migrates electrophoretically as an alpha-2 or beta globulin,<sup>110,247</sup> and contains one disulfide bridge<sup>308</sup> and a single terminal amino acid residue (alanine).<sup>274,308</sup> It has not been successfully dissociated into constituent subunits, and apparently is composed of a single polypeptide chain. The amino acid content of prothrombin has been determined.<sup>303,274</sup>

Prothrombin is present in human plasma in concentrations of approximately 10 to 15 mg/dl.<sup>140</sup> A major portion of the total body pool of this proenzyme is in the lymph<sup>89,96,491</sup> and other intravascular sites.<sup>461</sup> When purified <sup>131</sup>I-labeled prothrombin was infused into normal subjects, its disappearance was biphasic, with a rapid component ( $t_{1/2} = 8$  hours) reflecting equilibration with extravascular pools, followed by a slower component ( $t_{1/2} = 2.8$  days) that represents the true biologic half-life. The turnover rate was 2.4 mg/kg/day.<sup>461</sup> Similar figures have been obtained in patients with hereditary hypoprothrombinemia<sup>461</sup> (page 1177).

The hypothesis proposed by Seegers and his collaborators concerning the nature and function of prothrombin is discussed on page 426.

### Factor VII

Factor VII functions together with tissue factor in the extrinsic pathway of coagulation. The nature of the active form of this protein is uncertain. Studies of factor VII in preparations concentrated up to 8,000-fold have revealed a molecular weight that ranges from 48,000 to 100,000, depending on the source material and the exact methods employed.<sup>40,409</sup> Factor VII contains an unusually high concentration of carbohydrate, as much as 50% in some preparations<sup>409</sup>; it migrates electrophoretically as an alpha or beta globulin.<sup>383</sup> Its concentrations in human plasma have been estimated at 3 mg/dl<sup>410</sup>; it is also detectable in lymph.<sup>80,96,494</sup> There is preliminary evidence that this factor, or a subunit or precursor thereof, is produced or stored in the kidney.<sup>121,410</sup>

Factor VII apparently has the most rapid biologic turnover rate of any plasma protein. In patients with hereditary factor VII deficiency, the disappearance of infused factor VII is biphasic, and the biologic half-life ranges from four to six hours.<sup>82,215,316</sup> The reasons for the rapid catabolism are obscure.

### Factor IX

Factor IX is involved in the intrinsic pathway of coagulation. Evidence regarding the nature of its active form is inconclusive. Despite intensive effort, this protein has not been extensively purified or characterized chemically.<sup>392</sup> Purified bovine factor IX has a molecular weight of 55,000, and is composed of a single polypeptide chain.<sup>158a</sup> It contains approximately 26% carbohydrate.

Approximately 60% of the total body pool of factor IX is apparently extravascular.<sup>216</sup> This factor has been demonstrated in lymph,<sup>80,96,491</sup> but is present in the plasma in only trace amounts. Biphasic survival

curves with rapid and slow components are obtained when factor IX is infused into patients with hereditary deficiencies of this substance. The biologic half-life, as determined in such studies, is approximately 24 hours.<sup>61,216,330</sup> Estimates of the turnover rate obtained with <sup>35</sup>S-labeled plasma suggested much slower catabolism.<sup>11</sup>

### Factor X

Factor X is a proenzyme that is essential for the formation of prothrombinase in the common pathway of coagulation. It is activated by the products of both the intrinsic and extrinsic pathways.

The electrophoretic mobility of factor X ranges from that of an alpha globulin to that of a prealbumin.<sup>136</sup> Estimates of the molecular weight of human factor X have ranged from 50 to 100,000, depending on the purification method employed.<sup>283</sup> This variation may be the result of the tendency of this protein to aggregate in the presence of divalent cations.<sup>136</sup> Bovine factor X has a molecular weight of 55,000, and contains 10% carbohydrate.<sup>159,239</sup> It is composed of two polypeptide chains that have molecular weights of 38,000 and 17,000, respectively. All of the carbohydrate and the active serine moiety are found on the heavy chain; the light chain appears to be essential for the binding of factor X to phospholipids. Other studies<sup>312</sup> suggest that the native molecule is a single polypeptide chain. Bovine factor X can be chromatographically separated into two chemically different but functionally similar forms, which have been designated factors X<sub>1</sub> and X<sub>2</sub>.<sup>149,239</sup>

The biologic half-life of factor X, as determined in patients with hereditary deficiencies of this factor, ranges from 24 to 60 hours.<sup>61,82,379,437</sup> An initial rapid component was evident in the survival curves ( $t_{1/2} = 2-9$  hours). This observation, together with the presence of factor X in lymph,<sup>80,96,491</sup> implies the existence of significant extravascular pools. The plasma concentration of factor X has been estimated at 1.2 mg/dl.<sup>410</sup>

### Factor V

Factor V is essential for the formation of prothrombin in the common pathway of coagulation. The biochemical role of this trace protein in coagulation remains unclear.

The purification of factor V has proved difficult because of its *in vitro* lability. The molecular weight of purified human factor V is in excess of 200,000<sup>283</sup>; the bovine protein has a molecular weight of 290,000.<sup>139</sup> Active molecular subunits have been isolated by gel filtration; the larger fragments apparently contain phospholipids.<sup>47,397</sup> Factor V migrates electrophoretically as an albumin.

The *in vitro* activity of factor V is increased by the action of thrombin (page 429), Russell's viper venom,<sup>445</sup> and papain.<sup>401</sup> Factor V is unstable when stored in citrated plasma, and is rapidly inactivated *in vitro* by strong chelating agents such as EDTA and oxalate (page 430).

Factor V is synthesized in the liver.<sup>350</sup> In patients with hereditary deficiencies of this factor, the initial *in vivo* recovery of infused factor V is virtually complete, and the survival curve is monophasic.<sup>82,529</sup> Although these observations suggest the absence of significant extravascular depots of factor V, this factor has been identified in lymph.<sup>60,86,494</sup> Estimates of its biologic half-life have varied greatly, ranging from 12 to 36 hours.<sup>82,529</sup>

### Factor VIII

Factor VIII is a trace protein that is involved in the intrinsic pathway of coagulation. Its precise biochemical function in coagulation remains uncertain.

#### Biochemistry

Efforts to purify factor VIII have been hampered by its *in vitro* lability,<sup>79</sup> and difficulties in separating this protein from fibrinogen. It may be concentrated by cryoprecipitation (page 1186) and by gel filtration.<sup>425</sup> Studies of material purified up to 10,000-fold

with respect to plasma<sup>55,56,206,229,312,524</sup> suggest that the molecular weight of factor VIII is on the order of 2,000,000 or even higher, and that the molecule contains both carbohydrate<sup>207,254</sup> and lipid moieties.<sup>76,208</sup> Some investigators consider the lipid to be a contaminant.<sup>428</sup> The electrophoretic mobility of factor VIII is that of an alpha-2 or beta globulin.<sup>206</sup> Its activity is increased by certain phospholipases<sup>208</sup> and by low concentrations of thrombin (page 429). Like factor V, factor VIII is unstable in citrated plasma, and is rapidly inactivated by strong chelating agents.<sup>533</sup> (page 430).

Several workers have demonstrated the presence of active molecular subunits of factor VIII.<sup>206,534,535</sup> Those derived from the human protein have a molecular weight of approximately 250,000.<sup>312</sup> Bovine factor VIII may be dissociated into smaller subunits of molecular weight 103,000<sup>206</sup> which may be coupled to a larger "carrier" molecule in the circulation.<sup>355</sup> Preliminary studies have suggested that the major antigenic determinants of factor VIII may be located on a different molecular subunit than the active site concerned with coagulant activity. The precursor or subunit containing the antigenic sites is identical or related to the "anti-bleeding factor" which is deficient in von Willebrand's disease (page 1179).

#### Production

Despite extensive study, the sites of production of factor VIII have yet to be defined.<sup>206</sup> Most investigations have been concerned with the roles of the liver, the spleen, and the reticuloendothelial system.

Transplantation experiments in hemophilic dogs<sup>313,326,361,531</sup> provide evidence that factor VIII is synthesized in the liver. Thus, the transplantation of a normal liver into a hemophilic dog produced a significant increase in the factor VIII levels of the recipient animal<sup>313,531</sup>; in one experiment, levels in excess of 50% of normal persisted for as long as 140 days.<sup>313</sup> Hepatic venous blood contains more factor VIII than peripheral venous

blood.<sup>164</sup> There is little additional evidence for hepatic synthesis of factor VIII. Studies utilizing techniques such as specific immunofluorescence, experimental hepatic injury and extirpation, and extracorporeal<sup>121</sup> or in situ organ perfusion<sup>164</sup> have yielded inconclusive or contradictory results. The presence of normal or even high levels of factor VIII in patients with severe hepatocellular disease suggests that the hepatic cells are not the source of this factor. It may, however, be produced by the reticuloendothelial cells in the liver.

The importance of the *spleen* in the bio-dynamics of factor VIII is suggested by several observations. Thus, a significant increase in the plasma level of factor VIII has been demonstrated in both humans and dogs following epinephrine administration,<sup>234,434</sup> a response that is lacking in asplenic subjects.<sup>286</sup> Both heterotopic and orthotopic spleen transplants produce significant but transitory increases in the factor VIII levels of hemophilic dogs.<sup>313,326,361,531</sup> The results of splenic transplantation in one hemophilic patient were similar.<sup>192</sup> Splenectomy, however, does not affect the factor VIII levels of normal or hemophilic dogs or humans.<sup>178</sup> This evidence is compatible with the hypothesis that splenic synthesis of factor VIII is of minor physiologic importance, although the spleen may act as a significant storage site for this coagulation factor. Results of experiments in which asplenic normal dogs were cross-circulated with hemophilic dogs are consistent with this view.<sup>528,531</sup> Studies of organ perfusates suggest that the liver may produce a substance that "induces" factor VIII synthesis by the spleen.<sup>122</sup>

In one study, the infusion of homogenates of normal spleen into patients with factor VIII deficiency had the surprising effect of significantly increasing the factor VIII levels of the recipients for two to three months.<sup>113</sup> In another, in vitro factor VIII synthesis was attributed to normal lymphocytes and fibroblasts.<sup>548</sup> Both of these studies require confirmation.

The *reticuloendothelial system* as a whole has been implicated as the site of factor VIII

synthesis.<sup>530</sup> This hypothesis is difficult to prove or refute. The effects of total body irradiation on factor VIII levels of animals have been inconsistent,<sup>395,473,530</sup> and are difficult to interpret in any case. The transplantation of normal marrow into hemophilic dogs does not increase factor VIII levels,<sup>531</sup> even if the marrow graft is completely successful.<sup>490</sup>

Preliminary studies have suggested that the *kidney* also may participate in some way in the synthesis of factor VIII.<sup>45,121</sup> Thus, a small molecular weight protein, which exhibits factor VIII activity in vitro, has been isolated from kidney homogenates.<sup>45</sup> It was postulated that this protein may be a precursor or a subunit of factor VIII. Various succinylated proteins, including albumin,<sup>46</sup> have factor VIII-like activity in vitro. It has been suggested that "kidney factor VIII" represents such a protein.<sup>200</sup>

Information obtained from the study of von Willebrand's disease suggests that a humoral factor is in some way involved in factor VIII biosynthesis. This is discussed on page 1181.

In summary, available data would suggest that factor VIII originates in a system of cells that may be found in various organs. The liver appears to be the major source of this protein; the spleen apparently is the major storage site for this factor. It is not improbable that factor VIII production involves an interaction between two or more cellular or organ systems.

### Distribution and Turnover

The plasma concentration of factor VIII is on the order of 1  $\mu\text{g}/\text{dl}$ .<sup>140</sup> The in vivo distribution of this protein is poorly understood. The initial disappearance rate of factor VIII infused into hemophilic patients is rapid ( $t_{1/2} = 4$  to 6 hours). It has been assumed that this is due to the equilibration of the infused factor VIII with extravascular pools,<sup>11,470</sup> but there is little evidence for this hypothesis. Only small amounts of factor VIII are present in lymph,<sup>80,96,494</sup> and, in view of the large size of the molecule, rapid

extravascular distribution of infused factor VIII would seem unlikely.<sup>206</sup> The adsorption of factor VIII by platelets, other cells, or endothelium may explain this phenomenon, at least in part.

The slow component of the survival curve has a half-life of approximately 12 hours, and ranges from 8 to 18 hours in individual patients.<sup>3,82,406,470</sup> In many hemophiliacs, triphasic survival curves have been described, eg, a biphasic rapid initial loss of factor VIII, a rise following an initial rapid decrement of activity.<sup>3,390</sup> Data obtained with an *in vivo* protein labeling technique that employs <sup>35</sup>S-methionine suggest a much slower turnover rate for factor VIII (biologic  $t_{1/2}$  = 2.9 days) than do studies carried out in hemophilic patients. This discrepancy may be explained by the persistence within the circulation of inactive factor VIII.<sup>41</sup> Similar differences have been noted between the *in vivo* survival time of immunologically active factor VIII, and of functionally active factor VIII (page 1181).

### Factor XI

Factor XI is a proenzyme that is essential in the intrinsic pathway of coagulation. Surprisingly little is known concerning its biochemistry.<sup>187,369</sup> It is a trace protein that migrates electrophoretically as a beta or gamma globulin, and its molecular weight has been estimated at 50,000 to 200,000.<sup>140,285</sup> Its activated form may be eluted from the surfaces of particulate silicates such as celite.<sup>365</sup> Soybean trypsin inhibitor blocks the *in vitro* esterolytic activity of factor XIa, but does not affect its coagulant activity,<sup>359</sup> an observation which suggests that the proteolytic activity of factor XIa may not be related to its role in coagulation.

Plasma levels of factor XI frequently are diminished in patients with liver disease<sup>415</sup> (page 1205), but direct evidence for hepatic biosynthesis of this protein is lacking. Estimates of its biologic half-life obtained in patients with hereditary deficiency states have ranged from 48 to 84 hours.<sup>371,372,439</sup>

### Factor XII

Factor XII is activated by contact with foreign surfaces, and initiates the intrinsic pathway of coagulation. It also is involved in the activation of fibrinolysis (page 432) and in the plasma kinin system (page 440).

Factor XII of human origin has been purified extensively.<sup>423</sup> Its molecular weight is approximately 80,000,<sup>179</sup> and it migrates electrophoretically as a beta or gamma globulin.<sup>418</sup> Factor XII of bovine origin is a sialoglycoprotein,<sup>446</sup> but no carbohydrate was found in purified preparations of human factor XII.<sup>420</sup> Available evidence suggests that the *in vitro* esterolytic activity of this protein, like that of factor XIa, may be unrelated to its coagulant activity.<sup>419,423,468</sup>

The *in vivo* sites of synthesis of factor XII are unknown. The plasma levels of this factor usually are normal even in severe liver disease. The biologic half-life, as estimated in patients with hereditary deficiencies, ranges from 52 to 60 hours.<sup>248,515</sup>

### Factor XIII

The enzymatic form of factor XIII acts in the common pathway of coagulation where it forms stabilizing covalent bonds within fibrin strands. Factor XIII also may be involved in wound healing (page 440).

Factor XIII purified from human plasma is an alpha-2 globulin with a molecular weight of approximately 320,000. This protein can readily be dissociated into two pairs of subunits, ie, two alpha chains (MW 75,000) and two beta chains (MW 88,000).<sup>289,291,293,447</sup> It also is present in the platelets, and apparently is synthesized by the megakaryocytes<sup>250</sup> (page 378). Platelet factor XIII is composed of only two alpha chains, and has a molecular weight of 146,000.<sup>324,447</sup> Substances that exhibit factor XIII activity *in vitro* are present in a number of other tissues, and a transglutaminase, which is apparently unrelated to factor XIII of plasma origin, is found in liver homogenates.<sup>144,509</sup>

Plasma factor XIII is deficient in many patients with liver disease (page 1205), but

direct evidence for its hepatic biosynthesis is lacking. It has been suggested that this factor may be activated by the liver, or that an inhibitor of factor XIII arises as the result of liver disease.<sup>374</sup>

The biologic half-life of plasma factor XIII, as determined in patients with hereditary deficiency states, ranges from three to five days.<sup>87,233</sup>

### Tissue Factor

Homogenates of normal tissues markedly accelerate blood coagulation, a fact that was well known in the last century.<sup>304</sup> The responsible substance is termed "tissue factor" (factor III, thromboplastin).<sup>94</sup> It functions in coagulation by interacting with factor VII in the extrinsic pathway (Fig. 10-4).

The biochemistry of tissue factor is poorly understood.<sup>94,352</sup> It is a particulate complex of phosphatides, lipoproteins, and cholesterol,<sup>341,401</sup> which has a molecular weight of approximately 425,000.<sup>350</sup> Active tissue factor may be prepared from virtually any tissue; in homogenates it is found in the microsomal fraction.<sup>53,98</sup>

Tissue factor may be dissociated into its constituent lipoproteins and phosphatides by solvent extraction. Neither fraction is active in coagulation alone, but, when the two are recombined, full activity is restored.<sup>98,193,350</sup> The phosphatide fraction is composed of variable amounts of sphingosine, phosphatidylinositol, phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine.<sup>349</sup> The relative concentrations of these phosphatides do not appear to be critical insofar as the coagulant action of the complex is concerned; the structure and charge of the lipid moiety may be more important.<sup>168</sup> The action of tissue factor in coagulation is species specific, a characteristic that resides entirely in the protein moiety.<sup>237,350</sup> The relative coagulant activity of heterologous tissue factors in human plasma may have diagnostic significance, eg, in some of the variants of factor IX deficiency (page 1172). Some preparations of tissue factor exhibit enzymatic activity *in vitro*,<sup>352,402,412</sup> but this may be unrelated to their coagulant action.<sup>251</sup>

### Miscellaneous Coagulation Factors

There is evidence for the existence of several substances, in addition to the coagulation factors already discussed, that are active in coagulation. These include the Fletcher factor,<sup>190</sup> the Carr factor,<sup>95</sup> the Nishimine factor,<sup>546</sup> the Tatsumi factor,<sup>347</sup> the Dynia abnormality,<sup>302</sup> "thorium-vulnerable" factor,<sup>103,214</sup> "prephase" accelerator,<sup>149</sup> thromboplastin generation accelerator,<sup>389</sup> the "ADP-sensitive" factor,<sup>403</sup> and others.<sup>104,175</sup> Inherited disorders due to deficiencies of these "factors" are discussed on page 1183.

### Variations of Coagulation Factors in Health and Disease

#### Neonates

A moderate deficiency of the vitamin K-dependent coagulation factors (prothrombin and factors VII, IX and X) is present at birth.<sup>1,190,381</sup> Observed plasma levels vary widely, but usually range from 20 to 50% of those normally found in adults.<sup>1,180</sup> This apparently is the result of immaturity of the biosynthetic apparatus in the liver, and is unaffected by vitamin K given to the mother. The levels of these four factors fall even further during the first two to four days of the infant's life. This "secondary fall" is prevented if vitamin K is administered to either the mother or infant, and appears to represent the effects of a transient "physiologic" deficiency of the vitamin, which is probably attributable to a sterile gut or the absence of oral vitamin intake. Exaggeration of this phenomenon underlies hemorrhagic disease of the newborn (page 1201). Deficiencies of the vitamin K-dependent factors often are more pronounced in premature than in full-term infants, and vary in inverse proportion to gestational age and birth weight.<sup>88</sup>

Other abnormalities of coagulation may be "physiologic" in the newborn.<sup>1</sup> Thus, a qualitatively abnormal form of fibrinogen has been isolated from the plasma of normal newborns. Such *fetal fibrinogen* clots at an abnormally slow rate and differs chemically from adult fibrinogen in several respects.<sup>541</sup>

It disappears from the circulation during the first months of life.

Deficiencies of *factor XII*<sup>264</sup> and *factor XI*,<sup>210,372</sup> with levels ranging from 25 to 50% of adult norms, have been reported in normal infants; these deficiencies disappear within two to four weeks.<sup>264</sup> Assays for *factor XIII* have yielded variable results in the newborn.<sup>150</sup>

None of the coagulation abnormalities described above is of clinical significance in the normal neonate.

Plasma levels of *fibrinogen*, *factor V*, and *factor VIII* approximate adult norms in the normal neonate or thriving premature infant.<sup>1,189,373,381,457a</sup>

### Miscellaneous Variations

Virtually any disorder associated with stress, inflammation, or tissue necrosis may produce *hyperfibrinogenemia*. This may develop within a matter of hours, and is the major factor leading to an acceleration of the erythrocyte sedimentation rate in such disorders (page 125). *Hyperfibrinogenemia* also is seen in pregnancy,<sup>253</sup> following the administration of anovulatory medications,<sup>85</sup> and in hypermetabolic states.<sup>217</sup>

Increased plasma levels of *factor VIII* have been well documented in a large variety of situations.<sup>217,253</sup> Significant increases are consistently associated with various hypermetabolic states,<sup>217,472</sup> and have been attributed to hypersensitivity to catecholamines of endogenous origin.<sup>472</sup> *Factor VIII* levels also rise following vigorous exercise<sup>433</sup> and epinephrine administration.<sup>231,433</sup> The latter response presumably is the consequence of the release of *factor VIII* from the spleen.<sup>286</sup> A progressive rise in *factor VIII* levels is seen in pregnancy,<sup>253</sup> and persistent elevations are common in patients with chronic thrombocytopenia<sup>286</sup> and in those receiving oral contraceptives.<sup>108</sup> Neither splenectomy nor corticosteroids affect *factor VIII* levels.<sup>90</sup> Numerous other disorders have been associated with moderate increases in *factor VIII* levels.<sup>4,286</sup> The plasma levels of this factor normally are slightly greater in men than in women, and in persons of blood group A.<sup>407</sup>

The levels of the *vitamin K-dependent factors* are elevated in disorders associated with hypermetabolism, with the exception of *factor IX*, which is normal in hypermetabolic states even though it is diminished in myxedema.<sup>287,472</sup> These changes are associated with corresponding alterations in the turnover rate of these factors.<sup>287</sup> The levels of *factors VII, IX, and X* are increased in pregnancy, but prothrombin is little affected.<sup>253</sup> The administration of estrogenic and progestational hormones increases the levels of these factors to a variable extent.<sup>85,471</sup>

*Factor V* levels are unaffected by pregnancy<sup>253</sup> or hyper- or hypometabolism,<sup>472</sup> and are slightly if at all increased following exercise or epinephrine administration.<sup>157,232</sup>

*Factor XI* levels are diminished in hypothyroidism, but are normal in hyperthyroidism.<sup>472</sup> Plasma levels of this factor fall gradually during pregnancy.<sup>373</sup> Levels of *factors XI* and *XII* are markedly increased by exercise.<sup>132,231</sup> *Factor XIII* may decrease during normal pregnancy.<sup>108</sup>

## The Physiology of Blood Coagulation

The theories that have been proposed to explain the phenomena of blood coagulation are so numerous and varied that even a brief discussion of each is beyond the scope of the present section.<sup>59,62,110,137,304</sup> The discussion to follow will be based on a hypothesis that was independently presented in 1964 by MacFarlane<sup>200</sup> and by Davie and Ratnoff,<sup>109</sup> i.e., the "cascade" or "waterfall" hypothesis.

As originally conceived, this hypothesis viewed coagulation as an interlinked sequence of proenzyme-to-enzyme transformations.<sup>300</sup> Coagulation factors, which normally exist in the plasma as inert precursors, are transformed into enzymes when activated. These enzymes then convert the precursor next in line into its enzymatic form (Fig. 10-4, reactions 1, 2, 3). Each coagulation factor thus acts first as a substrate and then as an enzyme. The ability of small amounts of enzyme to activate large amounts of substrate in each successive step in the process was viewed as

a "biologic amplifier" of possible homeostatic importance.<sup>140</sup>

From the outset, the limitations of this formulation were apparent to its originators,<sup>301</sup> and several revisions of the coagulation "cascade" have since been made because of new information.<sup>301</sup> Despite continuing disagreement concerning the details of individual steps, the essential core of the cascade hypothesis remains widely accepted. Although highly theoretical, the scheme summarized in Figure 10-4 explains most available data, and continues to serve as a useful framework upon which new observations may be oriented.

### Pathways of Coagulation

Coagulation is initiated by two fundamentally different mechanisms, ie, the process of contact activation and the action of

tissue factor. It initially proceeds by two separate pathways that "converge" by activating a third common pathway leading to fibrin formation (Fig. 10-3).

Contact activation initiates a series of reactions involving factors XII, XI, IX, and VIII and platelet factor 3 (PF-3). These reactions lead to the formation of an enzyme that activates factor X; they proceed normally in the absence of tissue factor, and do not involve factor VII.<sup>10</sup> They are designated the *intrinsic pathway*.

When coagulation is initiated by tissue factor, an interaction between this substance and factor VII leads to the production of an enzyme that also activates factor X. This relatively simple process proceeds normally in the absence of factors XII, XI, VIII, and IX and PF-3, and does not require contact activation. It is termed the *extrinsic pathway*.

Subsequent steps in the process of coagu-

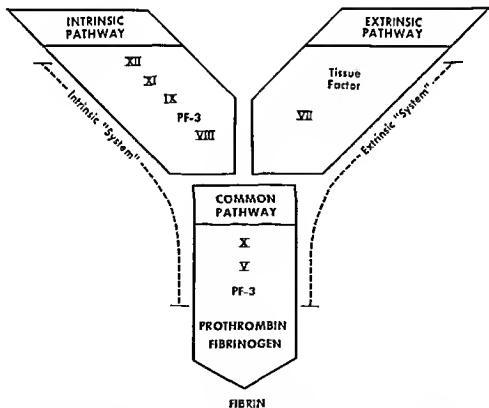

Fig 10-3. Pathways of coagulation. The terms *intrinsic* and *extrinsic "system"* are widely used with reference to the reactions indicated by dashed lines. PF-3 denotes platelet factor 3.

lation involve factors X and V, PF-3, prothrombin and fibrinogen. They proceed in essentially the same way whether factor X is activated by the product of the intrinsic pathway or the product of the extrinsic pathway. These reactions are termed the *common pathway*.

## The Intrinsic Pathway

### The Contact Phase

The phenomenon of *contact activation*<sup>219,522</sup> (*reaction 1*, Fig. 10-4) involves the adsorption of factor XII upon any of a variety of "active" surfaces, and results in a change in the conformation of this protein.<sup>125,365</sup> The nature of this change is uncertain, but it may involve an uncoiling of the molecule leading to the exposure of an enzymatically active site.<sup>184,521</sup>

Contact activation does not require calcium ions, and is produced in vitro by a variety of electronegative surfaces,<sup>228</sup> eg, glass, asbestos, particulate silicates such as Celite or kaolin, spider webs.<sup>369</sup> The amount of factor XII activated is proportional to the surface area of the activator. Thus, much greater activation results from a particulate activator than from a glass tube. Biologic surfaces that produce contact activation include collagen fibers,<sup>540</sup> unbroken skin,<sup>367</sup> sebum, long chain fatty acids,<sup>119,320</sup> uric acid,<sup>256</sup> homocystine,<sup>419</sup> and possibly fibrin and elastin.<sup>360</sup> Collagen presumably plays a major role in vivo. Chemical alterations of collagen that block or remove the free carboxyl groups of glutamic and aspartic acid abolish the ability of collagen to induce contact activation.<sup>540</sup> There is good experimental evidence that optimally spaced foci of negative charges are the critical determinants of both natural and artificial "active" surfaces.<sup>369</sup>

The nature of the interaction between factors XIIa and XI is unclear and controversial. This reaction occurs in the absence of ionic calcium, and involves the conversion of factor XI into XIa by factor XIIa. There is much to suggest that factor XIIa acts as an enzyme

in this reaction<sup>421</sup> (*reaction 2*), although the evidence is not conclusive.<sup>369,446</sup> Supporting evidence for this view has been obtained with purified factors XII and XI.<sup>421,427</sup> It has also been proposed that factors XIIa and XI interact to form a complex on the active surface, which then activates subsequent steps.<sup>179,422</sup> A third alternative is that factor XI functions as a cofactor for the enzymatic action of factor XIIa.<sup>137</sup>

There is general agreement that the product of the interaction between factors XIIa and XI (often termed *activation* or *contact product*) acts as an enzyme,<sup>301,369</sup> whatever its exact nature may be. In the next step (*reaction 3*), this substance and factor IX interact. Studies of the kinetics and stoichiometry of this reaction suggest that factor IX behaves as a substrate.<sup>93,368,442,443</sup> The reaction requires calcium ions, and is inhibited by heparin.

### The Activation of Factor X

The next step in the intrinsic pathway is the interaction between factor IXa, factor VIII, and PF-3 (*reaction 4*, Fig. 10-4). This step has proved very difficult to study, and remains poorly understood. There is general agreement on the following points: (1) it is calcium-dependent; (2) it requires traces of PF-3 or a platelet substitute<sup>444</sup>; (3) it is markedly accelerated by the action of traces of thrombin on factor VIII (page 429); and (4) it leads to the evolution of an enzymatic activity capable of activating factor X.

In the original cascade hypothesis<sup>300</sup> it was proposed that factor IXa converted factor VIII into its active form, which then activated factor X. Although this hypothesis cannot be dismissed, evidence for the existence of factor VIIIa or for the enzymatic activity of factor IXa is not entirely convincing.<sup>296,307,382</sup> Most evidence favors the view that factor IXa, factor VIII, calcium ions, and PF-3 form a complex by means of a unique physicochemical interaction.<sup>194,226</sup> In terms of this hypothesis, the phospholipid serves as a surface upon which coagulation factors and ions are adsorbed and oriented in such a

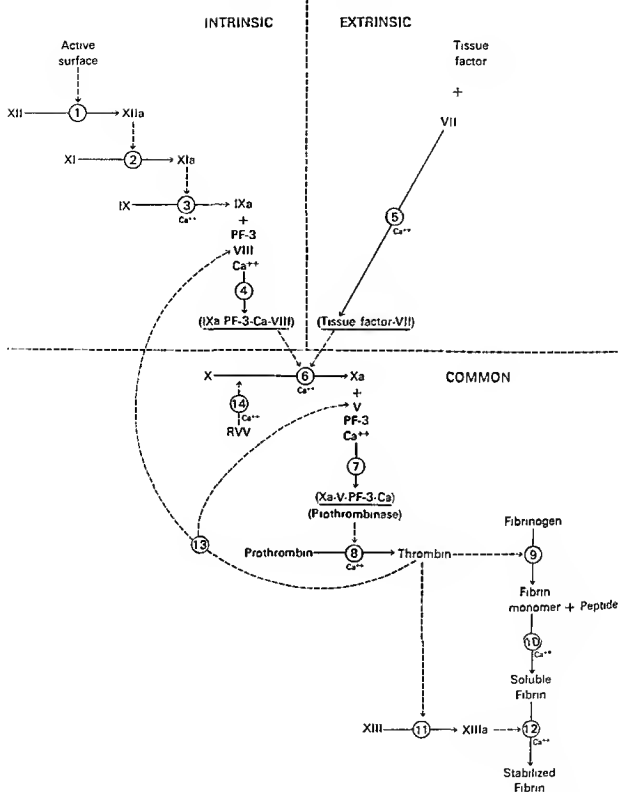

Fig. 10-4. The interactions of the coagulation factors. A modification of the cascade or waterfall hypothesis of MacFarlane<sup>100</sup> and of Davie and Ratnoff.<sup>101</sup> The three pathways of coagulation (Fig. 10-3) are separated by dashed lines. A solid arrow indicates transformation; a dashed arrow denotes action. Complexes are underlined and enclosed in parentheses, eg **(Xa V PF-3-Ca)**. Reaction numbers, indicated within arrows, are referred to in the text. The "autocatalytic" actions of thrombin (reaction 13) are illustrated in dotted lines. RVV is an abbreviation for Russell's viper venom (reaction 14).

manner that the resulting complex acquires enzymatic activity.<sup>97,200,382</sup> This reaction is quite similar to that believed to involve PF-3, factor V, and factor Xa in the common pathway (reaction 7).

Alternative hypotheses are quite consistent with most of the data. For example, factor IXa may directly activate factor X,<sup>137</sup> factor VIII acting as a cofactor.

### The Extrinsic Pathway

The extrinsic pathway involves only the interaction between tissue factor (factor III) and factor VII (reaction 5, Fig. 10-4). This requires the presence of calcium ions, and leads to the formation of a complex that is particulate<sup>91</sup> and behaves as an enzyme.<sup>348,369,539</sup> Studies of semi-purified preparations of bovine factor VII and tissue factor suggest that each of these components has discrete enzymatic activity,<sup>352,402</sup> but that the coagulant activity of the complex formed between them is the result of an autocatalytic degradation of factor VII that occurs following the attachment of factor VII to tissue factor.<sup>351</sup> An alternative view is that the major enzymatic activity resides in an "activated" form of tissue factor, and that factor VII acts mainly as a cofactor.<sup>137</sup>

There is some evidence that the extrinsic and intrinsic pathways interact. Thus, activation product, formed during the contact phase of the intrinsic pathway, appears to activate the extrinsic pathway by means of a poorly understood interaction with factor VII.<sup>22,244,459</sup> The contact factors also may interact with platelets, leading to the activation of the extrinsic pathway, as discussed on page 397. Activation of the intrinsic pathway by tissue factor and factor VII also may occur (page 439).

Since tissue factor contains phospholipids that act as platelet substitutes, additional PF-3 from platelets is not required for fibrin formation when coagulation is initiated by the extrinsic pathway, eg, in the measurement of the plasma prothrombin time (page 1056).

## The Common Pathway

### Formation of Prothrombinase

The common pathway of coagulation begins with the activation of factor X (reaction 6, Fig. 10-4). This step is calcium-dependent, and involves a proenzyme-to-enzyme transformation which is accomplished by the two different enzymatic activities that evolve from the reactions of the intrinsic and extrinsic pathways, respectively, as discussed above. The activation of factor X involves the cleavage of a peptide bond and the release of a glycopeptide of molecular weight 11,000.<sup>222</sup> Factor X also is activated by Russell's viper venom in the absence of other coagulation factors (reaction 14).<sup>141,299</sup> The active principle, purified from the crude venom, is a protease of small molecular weight.<sup>445,538</sup>

Activated factor X (factor Xa, thrombokinase,<sup>334</sup> product I, autoprothrombin C) is a relatively stable proteolytic enzyme, with a molecular weight of 44,000, that has been extensively studied in purified form.<sup>413a</sup> It contains a reactive serine moiety, splits synthetic esters, and activates trypsinogen.<sup>141</sup> Factor X also is "autocatalytically" activated upon storage, and in 25% sodium citrate.<sup>141,279</sup>

The interaction of factor Xa with factor V, Ca<sup>++</sup>, and PF-3 leads to the activation of prothrombin. There is much to favor the view that this reaction (reaction 7) involves the formation of a protein-phospholipid complex<sup>387</sup> termed *prothrombinase* (product II, prothrombin activator of the intrinsic or extrinsic system) in much the same manner as that formed from factor IXa, factor VIII, and PF-3 in the intrinsic pathway (reaction 4).<sup>194,200</sup> Prothrombinase is a particulate substance, and stable preparations of great potency have been isolated by ultracentrifugation. Such preparations may be dissociated, with recovery of activity corresponding to the original three components.<sup>47,241,251</sup> The kinetics of reaction 7 also are consistent with complex formation.<sup>198</sup> Factor Xa apparently

does not lead to the transformation of factor V into an active form,<sup>241</sup> as proposed in the original cascade hypothesis, but reaction 7 is accelerated by the action of traces of thrombin upon factor V (page 429).

There are several plausible alternatives to the hypothesis described above. Thus, purified preparations of factor Xa produce slow activation of prothrombin in the absence of calcium ions or other coagulation factors.<sup>241,336,489</sup> The addition of factor V and PF-3 increases the rate of this reaction<sup>336</sup> and that of esterolytic reactions involving factor X and synthetic substrates.<sup>102</sup> These observations are consistent with the hypothesis that factor V and PF-3 act mainly to accelerate or facilitate the enzymatic action of factor Xa,<sup>137</sup> either by increasing the "susceptibility" of the prothrombin molecule to the proteolytic action of factor Xa,<sup>145,241</sup> or by increasing the affinity of factor Xa for labile bonds in prothrombin.<sup>102</sup>

### Prothrombin Activation

The conversion of prothrombin into thrombin (reaction 8) is calcium-dependent and, when studied in whole blood *in vitro*, is relatively slow but usually complete, i.e., all the prothrombin normally is converted into thrombin.<sup>396,526</sup> The limiting factor appears to be the amount of PF-3 available for reaction 7.<sup>396</sup> Prothrombinase apparently splits the prothrombin molecule in two places,<sup>309</sup> resulting in the transformation of a single polypeptide chain into a molecule composed of two chains of unequal size interconnected by a single disulfide bridge<sup>308,309</sup> (Fig. 10-5, I). This results in the release of peptide material and possibly carbohydrate, a decrease in molecular weight from 69,000 to approximately 34,000, and the evolution of a new terminal amino acid residue.<sup>240,308,309</sup>

### The Seegers Hypothesis

A longstanding and often acrimonious controversy has surrounded the nature of prothrombin and its role in blood coagulation. Over a period of several years, Seegers

and his many collaborators have evolved the hypothesis that the prothrombin molecule is in essence a "molecular system."<sup>450,451</sup> As viewed by these workers, factors VII, IX, and X have no identity as such in plasma, but rather are derived autocatalytically from the parent prothrombin molecule during coagulation.<sup>454</sup> The derivative molecules, which correspond to the activities of factors VII, IX, and X, have been named autoprothrombins I, II, and III; their active forms are designated autoprothrombins A, B, and C. Seegers et al maintain that prothrombin itself is sensitive to surface contact, and dispute the existence of factor XI.

Just as the cascade hypothesis has undergone revision in the past 10 years, the full thrust of Seegers' original hypothesis has been modified in at least three respects (Fig. 10-6): (1) a discrete substance, which gives rise to no other coagulant activity, is now recognized as the immediate precursor of thrombin (prethrombin); (2) the conversion of autoprothrombin III into autoprothrombin C (factor X into factor Xa) is now recognized as a separate and distinct step that occurs prior to "prethrombin" activation; and (3) the role of tissue factor and autoprothrombin I (factor VII, now termed "cothromboplastin") in the activation of autoprothrombin III is now recognized.<sup>33,450,455,457</sup>

The differences between this revised hypothesis and recent versions of the cascade hypothesis (Fig. 10-4) are thus not as great as they once seemed to be.<sup>304</sup> Two major areas of controversy remain. The Seegers hypothesis does not provide an explanation for the role of factor IX in coagulation,<sup>454,456</sup> and maintains the view that the four vitamin K-dependent coagulation factors originate from a single plasma precursor, the "prothrombin complex."<sup>455,457</sup> The evidence cited for the latter premise is derived largely from experiments in which purified prothrombin is slowly activated in 25% sodium citrate.<sup>452</sup> There is now good evidence that prothrombin prepared by methods different from those employed by Seegers<sup>452</sup> does not undergo "autocatalytic" activation in cit-

Fig. 10-5. Proteolytic phenomena in blood coagulation. Polypeptide chains of proteins are represented by solid blocks. Asterisks (\*) denote the active centers of thrombin and plasmin. S S denotes disulfide bonds.

I. The activation of prothrombin by prothrombinase. This involves the cleavage of two bonds, yielding peptide material and thrombin, which contains two chains (A and B). The activation of prothrombin by prothrombinase involves the cleavage of two bonds, yielding peptide material and thrombin, which contains two chains (A and B). The activation of prothrombin by prothrombinase involves the cleavage of two bonds, yielding peptide material and thrombin, which contains two chains (A and B).

II. The proteolytic action of thrombin on fibrinogen. This involves the cleavage of four arginyl-glycine bonds and yields fibrin monomer and four small peptides, two from the alpha chains (fibrinopeptides A) and two from the beta chains (fibrinopeptides B). The reduced negative charge on the terminal ends of the alpha end beta chains of fibrin monomer initiates polymerization.

III. The activation of plasminogen by urokinase. This involves the cleavage of a single arginyl-valine bond, yielding a molecule containing a heavy chain (MW = 49,000) and a light chain (MW = 26,000) interconnected by a single disulfide bond. Although activation requires the cleavage of only one bond, there is significant peptide loss, and a second bond presumably is cleaved.

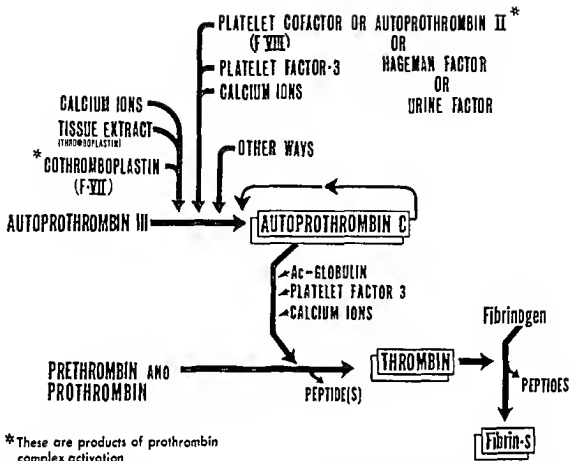

Fig 10-6 Blood clotting mechanisms, according to the Seegers hypothesis. Three basic reactions in blood clotting are represented. Thrombin alone as a proteolytic enzyme produces fibrin. Autoprothrombin C, another proteolytic enzyme, forms thrombin from its precursor. This function of autoprothrombin C is accelerated in a rather specific manner by plasma Ac-globulin, platelet factor 3, and calcium ions. The formation of autoprothrombin C can occur spontaneously, and is accelerated in various ways. Acceleration occurs with calcium ions, tissue thromboplastin, and cothromboplastin (F-VII). The latter group of accelerators tends to lead to complete consumption of autoprothrombin III. Less intensive acceleration is obtained with calcium ions and platelet factor 3 alone or with platelet factor 3, calcium ions, plus platelet cofactor (F-VIII) or instead of platelet cofactor, another platelet cofactor called autoprothrombin II (F-XII) or, in like manner, Hageman protein (F-XIII) or a fraction from urine. There are other ways to form autoprothrombin C. Furthermore, the supplementation of platelet factor 3 activity by any one of the platelet cofactors neither requires nor excludes a preferred sequence in which the platelet cofactor activity occurs (Diagram kindly provided by Dr. Walter Seegers).

rate and that the latter phenomenon, when observed, is a consequence of autocatalytic activation of contaminating factor X.<sup>236,279,308</sup> Furthermore, much of the biochemical data cited elsewhere in this chapter, a large body of immunologic evidence,<sup>110,247</sup> and numerous studies of the hereditary coagulation disorders (Chapter 37) suggest that prothrombin and factors VII, IX, and X are different proteins. Although these data are very difficult to reconcile with the Seegers

hypothesis, available evidence does not justify dogmatic views on either side of this controversy, which must be regarded as unsettled.<sup>304</sup>

### The Thrombin-Fibrinogen Reaction

The last phase of coagulation involves the conversion of fibrinogen into stabilized fibrin, and occurs in three distinct steps<sup>271,462</sup> (Fig. 10-4).

### The Enzymatic Step

Thrombin is a potent proteolytic enzyme that contains a reactive serine moiety at its active center.<sup>167</sup> The molecular weight of purified human thrombin is approximately 34,000.<sup>308,309</sup> Active components with monomeric molecular weights as low as 5,000 have been isolated from bovine thrombin.<sup>48,183,438</sup> Under physiologic conditions, the proteolytic action of thrombin is limited to the cleavage of four arginyl-glycine bonds in fibrinogen<sup>271,462</sup> (Fig. 10-5, II). Thrombin also splits this bond in synthetic esters,<sup>462</sup> but not in many other proteins.<sup>37</sup> This limited specificity appears to be conferred by the location of the enzyme-binding sites on fibrinogen,<sup>71,344</sup> although secondary binding sites on the enzyme remote from its active center may be important.<sup>290</sup> The binding sites on thrombin may be altered without affecting the active center of the enzyme, eg, by acetylation, which abolishes the coagulant activity of thrombin but preserves its esterolytic activity.<sup>275</sup>

The proteolytic action of thrombin on fibrinogen occurs normally in the absence of  $\text{Ca}^{++}$ , and releases four fibrinopeptides per mole of fibrinogen (two each of peptides A and B) (Fig. 10-4, reaction 9). The residual molecule is termed *fibrin monomer*. There is no substantial evidence that carbohydrate moieties are removed from fibrinogen during coagulation.<sup>131,414</sup>

### The Polymerization Step

Because of the loss of acidic peptides, the electronegativity of fibrin monomer is diminished significantly, and the intermolecular repulsive forces between fibrin monomers are diminished. Hydrogen bond donors and acceptors also may be exposed as the result of the removal of the fibrinopeptides, but changes in the conformation of the fibrinogen molecule do not occur.<sup>290</sup> As a result of these processes, polymerization begins. Fibrin polymerization is a complicated physical phenomenon that is still poorly understood.<sup>131,262a,268,462</sup> It apparently involves a

marked change in the ionization of amino acid side chains, and is associated with significant heat production.<sup>134</sup>

Polymerization first leads to the formation of *soluble fibrin* (reaction 10), a term that refers to fibrin formed prior to the action of factor XIII, or in purified systems lacking this proenzyme. This process is reversible *in vitro*, and involves primarily the formation of hydrogen bonds between fibrin monomers.<sup>134,462</sup> As a consequence, soluble fibrin is mechanically fragile, and dissociates into its constituent monomers in the presence of inhibitors of hydrogen bonding, such as urea or monochloroacetic acid.<sup>130,507</sup>

### The Stabilization Step

In the stabilization step, the last in the thrombin-fibrinogen reaction, soluble fibrin is converted into *insoluble* or *stabilized fibrin* by factor XIIIa (reaction 12).<sup>288,289,293</sup> This enzyme is formed from its inert precursor by the action of thrombin (reaction 11). This involves removal of a peptide of MW 4,000 from the alpha chain of the proenzyme.<sup>447</sup> Factor XIIIa ("fibrinolygase") is a transamidase that forms covalent bonds between the epsilon amino groups of lysine and the gamma amide groups of glutamine.<sup>294,460</sup> The transamidation step requires calcium, but the activation of human factor XIII by thrombin apparently does not.<sup>508</sup>

Under the electron microscope,<sup>183</sup> stabilized fibrin reveals a characteristic axial periodicity of 226 nm, which is not present in soluble fibrin. This may be due to rearrangement during stabilization of fibrin monomers in a "staggered" side-by-side manner.<sup>40</sup> Structurally, fibrin resembles the proteins of muscle and skin. Insoluble fibrin provides an extremely strong and stable framework for the "permanent" hemostatic plug.

### Miscellaneous Coagulation Phenomena

#### Autocatalytic Action of Thrombin

The rate of prothrombinase production via the intrinsic pathway is initially relatively

slow. However, once traces of thrombin evolve, the rate of these reactions increases greatly, ie, the production of prothrombinase and hence of thrombin becomes "autocatalytic." This phenomenon has been recognized for many years<sup>502,527</sup> and is now thought to be the result of an interaction between thrombin and factors V and VIII (*reaction 13*, Fig. 10-4).<sup>64,212,251,416</sup> Traces of thrombin increase the activity of factor VIII by 80-fold.<sup>416</sup> The activity of factor V increases 15- to 30-fold, but more thrombin is required.<sup>212</sup> High concentrations of thrombin inactivate both factors

The autocatalytic role of thrombin has been viewed as the process that "shifts coagulation into high gear."<sup>416</sup> This may be homeostatically important, since the rapid evolution of a massive coagulum may be essential for hemostasis following large injuries

### Role of Metal Ions

Calcium ions are required for all reactions in the coagulation phase except those of the contact phase involving factors XII and XI (Fig. 10-4, *reactions 1 and 2*), and the enzymatic effects of thrombin on fibrinogen (*reaction 9*) and factor XIII (*reaction 12*). Calcium ions apparently act as nonspecific accelerators of fibrin polymerization, but are not an absolute requirement for this step (*reaction 10*).<sup>425</sup>

The exact biochemical role of this divalent ion in these diverse reactions remains obscure. There is indirect evidence that calcium functions in an adsorbed rather than in an ionic form, where it may act to maintain optimal surface charge, or to stabilize the subunit structure or conformation of procoagulant proteins, phospholipids, or complexes thereof.<sup>294,402</sup>

The removal of trace metal ions by strong chelating agents such as EDTA markedly alters the in vitro stability of factors V and VIII<sup>533</sup> and possibly fibrinogen as well.<sup>169,549</sup> There is no evidence, however, that any of these factors are true metalloproteins. The marked impairment of fibrinogen reactivity produced by EDTA apparently is not the

result of the removal of essential trace ions.<sup>67,169</sup> The rapid in vitro inactivation of factors V and VIII by EDTA is poorly understood.<sup>533,549</sup>

### Consumption of Coagulation Factors

The coagulation factors have long been separated into two groups on the basis of their presence or absence in serum (Table 10-2), ie, those that are utilized or consumed during in vitro coagulation (fibrinogen, prothrombin, factors V, VIII, and XIII), and those that are not (factors VII, IX, X, XI, and XII). At least three different phenomena may be involved in the in vitro "consumption" of coagulation factors: (1) the factors may be converted stoichiometrically into their "active" forms, eg, fibrinogen and prothrombin; (2) the active forms may be adsorbed into fibrin and thus removed from serum with the clot, eg, factor XIII<sup>202</sup>; and (3) the factors may first be activated by thrombin, as discussed above, and then consumed in an undefined manner, eg, factors V and VIII.

When unphysiologic concentrations of activators are employed, factors that normally remain in serum are consumed.<sup>368</sup> For example, factor X is completely utilized when excess factor VIII is present<sup>306</sup>; factor IX is consumed in the presence of large concentrations of Celite.<sup>365,523</sup> Serum free of all coagulation factors has been prepared by such methods. Conversely, when certain factors are deficient, substances normally "consumed" are not utilized,<sup>458</sup> ie, factor V consumption is reduced in blood deficient in factors VIII and IX.<sup>126</sup> This phenomenon provides the basis for the prothrombin consumption test (page 1059).

## Homeostatic Control Mechanisms

As has been discussed, the proenzymes involved in the process of coagulation are present in great excess, minute concentrations of coagulant enzymes activate large amounts of their substrates, and, once initiated, coagulation becomes autocatalytic. Because these

phenomena lead to biologic "amplification" of the processes of coagulation, counterforces of equal potency are needed to limit the hemostatic plug to desirable size and to neutralize active procoagulants that may enter the general circulation. Such control mechanisms operate at three different physiologic "levels," ie, locally in the hemostatic plug, in the general circulation, and in various cellular clearance mechanisms residing in the reticuloendothelial system, the liver, and the lung.

### Local Processes

Blood flow, per se, acts to restrict the propagation of blood clots; active coagulants are washed away from the site of injury and are greatly diluted in the process. Fibrin forms a firm seal over injured vascular surfaces and contiguous normal endothelium, thus restricting active coagulants to the interior of the hemostatic plug. The role of the platelet in limiting the extension of the hemostatic plug is discussed on page 399.

The confusing term "antithrombin I" refers to the capacity of fibrin to adsorb or occlude thrombin.<sup>257,413</sup> This phenomenon is a unique form of product inhibition of an enzymatic reaction, and may neutralize a surprisingly large amount of thrombin. For example, as many as 1000 units of thrombin can be adsorbed by the fibrin formed from 1 ml of plasma. The thrombin so adsorbed is not inactivated; it can be recovered, essentially unaltered, by extraction of the clot, or may reappear slowly during clot retraction<sup>204</sup> or fibrinolysis.<sup>449</sup> The ability of a fibrin mass to rapidly and instantaneously adsorb large amounts of thrombin at the site of its production suggests that "antithrombin I" may be of great physiologic significance.

### Humoral Inhibitors

Several substances that act as inhibitors of coagulation *in vitro* have been demonstrated in normal plasma. The *in vivo* action and the homeostatic importance of such humoral inhibitors of coagulation remain unclear.<sup>204</sup>

### Antithrombins

Six antithrombins have been designated with Roman numerals, but it has become apparent that only "antithrombin I," which is not a humoral inhibitor and is discussed above, and antithrombin III are clearly of physiologic importance. Antithrombin II is the heparin cofactor, which is discussed on page 1239; antithrombin VI represents the effects of various fibrin degradation products (FDP), which are discussed on page 436. Antithrombins IV<sup>338</sup> and V<sup>318</sup> are of uncertain physiologic significance.

### Antithrombin III

Antithrombin III is a plasma protein that inactivates thrombin by means of an irreversible time-dependent reaction, and thus is often designated "progressive" antithrombin. It has been purified extensively,<sup>6,204</sup> and has been separated from two other "progressive" antithrombins,<sup>9</sup> which are discussed below. Antithrombin III is an alpha-2 globulin that has a molecular weight of 64,000.<sup>7</sup> It apparently is produced in the liver, and is found in various extravascular sites as well as in the plasma.<sup>204</sup>

The reaction between antithrombin III and thrombin has been carefully studied,<sup>172,205,358</sup> but the biochemical mechanism of thrombin inactivation remains obscure. Kinetic studies suggest that the reaction is bimolecular,<sup>7,204</sup> but unexplained inconsistencies in the stoichiometry have been encountered.<sup>257</sup>

Antithrombin III inactivates, in addition to thrombin, factor Xa,<sup>65,314,545</sup> factor VII,<sup>133</sup> plasmin, and possibly tissue factor<sup>133</sup>; its action is inhibited by platelet factor 2 (page 397). Most evidence would suggest that this inhibitor is identical or closely related to antithrombin II,<sup>9</sup> although this view has been questioned.<sup>160</sup>

### Miscellaneous Antithrombins

A second "progressive" antithrombin normally present in plasma is an alpha-2-macroglobulin.<sup>8,9</sup> This protein acts more slowly than antithrombin III, forms complexes with

of proteolytic enzymes other than thrombin, and inactivates plasmin<sup>161</sup> (page 435). A third progressive antithrombin (*alpha-1-trypsin inhibitor*) is normally present in plasma. Fibrinopeptides may act as antithrombins.<sup>189</sup>

### Miscellaneous Coagulation Inhibitors

Two inhibitors of factor XIa (contact product) have been isolated from normal plasma. One is an alpha globulin and has a molecular weight of 40,000 to 50,000<sup>354,370</sup>; preliminary studies suggest that this substance also inactivates factor Xa.<sup>143</sup> The other is an inhibitor of the first component of complement.<sup>44</sup>

Other "physiologic" inhibitors of coagulation include substances in the plasma that inactivate factor IXa,<sup>133</sup> prothrombinase,<sup>115</sup> and tissue thromboplastin.<sup>273</sup> Various lipid inhibitors have been isolated from normal blood and tissues,<sup>250</sup> including some that may participate in the inactivation of factor VIII.<sup>173,311</sup> The role of humoral inhibitors in the pathogenesis of hemophilia A is discussed on page 1161.

### Cellular Clearance Mechanisms

The removal of activated coagulants from the circulation by the liver has been demonstrated both directly and indirectly.<sup>116,483</sup> The reticuloendothelial depots in this organ<sup>26</sup> remove mainly particulate material, eg, prothrombinase,<sup>484</sup> tissue thromboplastin, certain fibrinogen degradation products.<sup>163</sup> Soluble coagulants, such as the stable enzymes, that are present in serum in high concentrations (factor IXa, factor Xa, factor VII<sup>117,479,481</sup>), also are cleared from the circulation by the liver, but appear to be taken up by the hepatic cells, possibly by means of conjugation with cell-associated inhibitors.<sup>118</sup> All of these factors are glycoproteins, and it is not improbable that, as with many other plasma proteins,<sup>339</sup> the loss of terminal sialic acid moieties during activation results in their removal from the circulation.<sup>117,536</sup>

Finely particulate fibrin<sup>281</sup> and tissue fac-

tor<sup>32</sup> may be removed from the circulation in the *pulmonary vascular bed*. Circulating *leukocytes* also may participate in the clearance of hemostatic "debris."

The "autoblockade" of these clearance functions is an essential part of the Shwartzman phenomenon in animals, and may be of pathophysiologic importance in intravascular coagulation in man (page 1211).

## The Fibrinolytic Enzyme System

Fibrinolysis results from the conversion of an inert plasma proenzyme (plasminogen) into a proteolytic enzyme (plasmin) whose main physiologic role presumably is the proteolytic dissolution of fibrin. Plasminogen and plasmin, together with activators and inhibitors of the process, comprise the fibrinolytic enzyme system (Fig. 10-7). Fibrinolysis is usually considered to be the major physiologic means of disposing of fibrin after its hemostatic function has been fulfilled; it would thus be of paramount importance in wound healing and the recanalization of thrombosed vessels.<sup>266</sup> However, other mechanisms of fibrin removal, such as phagocytosis, may be of equal importance.<sup>41,285</sup> Knowledge concerning fibrinolysis is now extensive<sup>143,151,358,391,467</sup> but, like coagulation, it has been studied largely by *in vitro* techniques. The details of the process as it occurs *in vivo* are only now becoming clarified.

- The therapeutic activation of the fibrinolytic enzyme system (thrombolytic therapy) and abnormalities of the system that may be of pathophysiologic importance in thrombosis are discussed in Chapter 39. The pathophysiologic role of fibrinolysis and fibrinogenolysis in various bleeding disorders is summarized in Chapter 38.

### Components of the System

#### Plasminogen

Plasminogen is a beta globulin, of molecular weight 81,000, which is composed of a

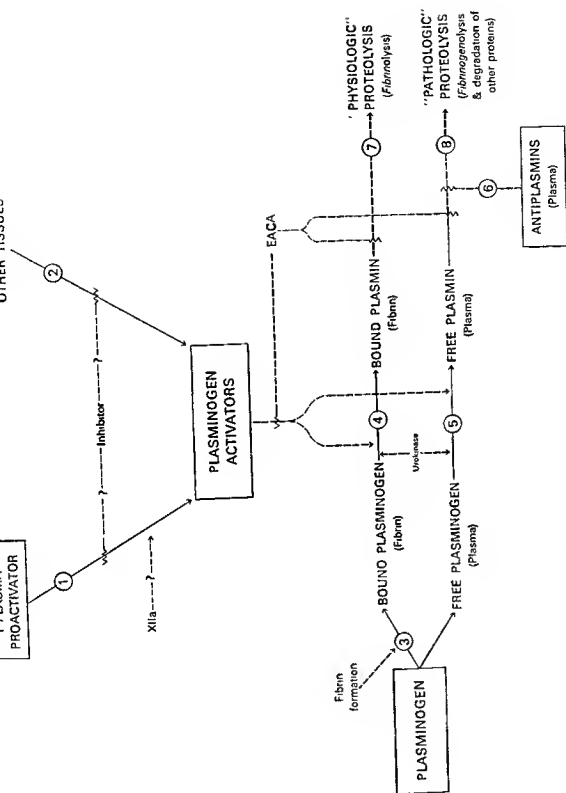

Fig 10.7 The physiology of fibrinolysis (essentially as proposed by Sherry<sup>415</sup>). Solid arrows denote transformation; dashed arrows denote action. The steps numbered within arrows are referred to in the text. The physiologic importance of steps or components designated with question marks has not been definitely established. EACA is an abbreviation for epsilon amino-caproic acid.

single polypeptide chain.<sup>2,17,435,496</sup> It is present in the plasma in concentrations ranging from 10 to 20 mg/dl.<sup>465</sup> Evidence that it is synthesized in the liver is largely indirect, and there is preliminary evidence that it is produced or stored in the eosinophils of the bone marrow, and may be transported in the circulation within these cells.<sup>43,356,408,431</sup>

Plasminogen forms complexes with fibrinogen,<sup>39</sup> and, when fibrin forms, large amounts of plasminogen are adsorbed or occluded within the fibrin mass.<sup>430</sup>

### Plasmin

The biochemical properties of plasmin (fibrinolysin) vary, depending on the means by which this substance is activated.<sup>19,496</sup> Urokinase activation involves the cleavage of a single arginyl-valine bond<sup>435</sup> and the conversion of a long polypeptide chain into a molecule composed of two chains<sup>436,495,496</sup> held together by a single disulfide bond (Fig. 10-5, III).

Unlike thrombin, plasmin has a wide spectrum of proteolytic activity that is quite comparable to that of trypsin.<sup>467</sup> It cleaves arginyl-lysine bonds in a large variety of substrates including synthetic esters, hormones, various components of complement,<sup>391,467</sup> and several coagulation factors including fibrinogen<sup>123,477</sup> (page 1225).

Plasmin is very short-lived in plasma, owing to its inactivation by humoral antiplasmins. There is preliminary evidence that a complex composed of plasmin and antiplasmin of the alpha-2 macroglobulin variety may normally circulate in the plasma.<sup>188</sup>

### Plasminogen Activators

The term "plasminogen activators" refers to a heterogeneous group of substances that convert plasminogen into plasmin. Such plasminogen activators apparently are proteolytic enzymes,<sup>469</sup> but their biochemistry is poorly understood. They are concentrated in the lysosomes of most cells<sup>345</sup> and in the vascular endothelium<sup>16,505</sup> (*tissue activators*, *fibrinolytic enzymes*, *cytokinases*). The concentration

of endothelial activators is greatest in the vessels of the microcirculation, particularly in small veins and in the renal vasculature.<sup>223,323</sup> Relatively little plasminogen activator is found in large vessels. Plasminogen activators also have been isolated from leukocytes<sup>114</sup> and platelets,<sup>171,177</sup> and there is preliminary evidence that thrombin may activate plasminogen directly.<sup>83,135</sup>

Plasminogen activators normally are present in trace amounts in the plasma. There is indirect evidence that such *blood activators* originate from the endothelium, and enter the general circulation where they survive only transiently because of rapid removal by the liver.<sup>153</sup>

*Urokinase* is a plasminogen activator that has been isolated from urine and extensively purified.<sup>281</sup> It is a polypeptide, of molecular weight 54,000,<sup>281</sup> that cleaves arginyl-lysine bonds in plasminogen and in a variety of other substrates. Urokinase apparently is not, as previously supposed, an excretion product derived from plasminogen activators in the blood.<sup>222,263</sup> There is preliminary evidence that it is synthesized in the kidney.<sup>263</sup>

Plasminogen activators also are present in other body fluids, eg, milk,<sup>33</sup> tears,<sup>491</sup> saliva,<sup>15</sup> and semen.<sup>510</sup> These activators, and urokinase as well, may play a physiologic role in maintaining the patency of excretory ducts.<sup>328</sup>

### Plasminogen Proactivator

Evidence for the existence of an inert precursor of blood plasminogen activator (*plasma proactivator*) was first obtained from studies of plasminogen activation by streptokinase. These studies suggested that this bacterial enzyme activated plasminogen only after a preliminary interaction with an unidentified plasma euglobulin<sup>258,467</sup> (Fig. 10-7, *step 1*). A further study of this phenomenon, however, provided an alternative explanation for the data; ie, the plasma factor involved was plasmin, which, in the form of a complex with streptokinase, is capable of autocatalytically activating more plasminogen.<sup>258</sup> This hypothesis, in turn, has been criticized,<sup>469</sup> and

the mechanism of plasminogen activation by streptokinase remains controversial.<sup>112,259,497</sup>

Supporting evidence for the presence of a plasma proactivator has been obtained from studies demonstrating the ability of factor XIIa to activate fibrinolysis.<sup>230,353</sup> In vitro studies with purified factor XII suggest that plasminogen activation occurs only in the presence of one or possibly two plasma proteins that are distinct from factor XI and plasma kallikrein.<sup>252,377</sup> In vivo studies in patients with factor XII deficiency provide indirect support for this hypothesis.<sup>320,321,232</sup> Fibrinolysis, like coagulation, may thus be activated by both extrinsic (tissue-activated) and intrinsic (contact-activated) pathways.

## Inhibitors of Fibrinolysis

### Antiplasmins

At least two plasma proteins specifically neutralize free plasmin.<sup>362,363</sup> These are an alpha-2-macroglobulin, which neutralizes plasmin rapidly, and a slowly acting alpha-1 globulin (alpha-1-antitrypsin).<sup>432</sup> The alpha-2-macroglobulin is a competitive inhibitor of both thrombin and plasmin, and competition between these two enzymes for binding sites on the inhibitor molecule may be homeostatically important in intravascular coagulation<sup>161</sup> (Chapter 38).

The kinetics and stoichiometry of the plasmin-antiplasmin reaction have been studied intensively. In plasma, the total antiplasmin activity normally exceeds the available plasmin by at least 10-fold.<sup>363</sup> There is indirect evidence that antiplasmins are synthesized in the liver,<sup>511</sup> but data concerning their biodynamics are inadequate.

Antiplasmins also have been isolated from the platelets,<sup>243</sup> and from mesothelium and endothelium<sup>411</sup>; the physiologic significance of these tissue-associated antiplasmins remains uncertain. Various plasma lipids exhibit antiplasmin activity in vivo and in vitro, an observation of possible physiologic and pathologic significance.<sup>129,331</sup>

Natural inhibitors of plasminogen activa-

tion also have been demonstrated in the plasma.<sup>53</sup>

### Artificial Inhibitors

A number of chemical agents have been shown to inhibit fibrinolysis.<sup>165,343</sup> Some of these have found therapeutic utility in man, eg, epsilon aminocaproic acid [EACA],<sup>20</sup> tranexamic acid,<sup>127</sup> Trasylol.<sup>129</sup> These are discussed briefly on page 1226.

## The Physiology of Fibrinolysis

### Release of Activator

Most of the physiologic and pathologic stimuli that lead to the release of plasminogen activators in vivo are vasoactive<sup>105,145,218</sup> and presumably lead to the release of endothelial activators (Fig. 10-7, step 2), eg, exercise,<sup>91</sup> electric shock and other forms of stress,<sup>440</sup> epinephrine, histamine,<sup>219</sup> bacterial pyrogen,<sup>144</sup> intravenous nicotinic acid,<sup>153</sup> ischemia, and hypoxia.<sup>267,440</sup> Lysosomal activators also may be released under physiologic circumstances,<sup>50</sup> and in pathologic processes involving shock or tissue damage. The physiologic importance of plasminogen activated "indirectly" by factor XIIa, or directly by thrombin, is uncertain. Fibrinolytic activity normally is much greater in the microcirculation than in the general circulation,<sup>223</sup> presumably because of the release of endothelial activators.

### Plasminogen Activation

The consequences of plasminogen activation are greatly modified by the tendency of fibrin to adsorb this proenzyme.<sup>20,467</sup> Thus, when fibrin forms (Fig. 10-7, step 3) and plasminogen is activated (steps 4 and 5), plasmin exists in both free and fibrin-adsorbed forms. Free plasmin normally is destroyed as rapidly as it is formed by antiplasmins in the plasma (step 6), and hence is unable to proteolytically degrade any of its many susceptible substrates. Fibrin-bound plasmin, to the contrary, is little affected by the antiplasmins

in the plasma, and thus is free to carry out its presumed physiologic function, the lysis of fibrin (step 7). The fact that antiplasmins are ineffective within a fibrin thrombus is unexplained, although there is some evidence that these inhibitors are unable to diffuse into a fibrin mass as rapidly as can plasminogen activators.<sup>542</sup>

The proteolytic degradation of fibrinogen, other coagulation factors, and plasma proteins (step 8) occurs only if free plasmin exceeds the capacity of its plasma inhibitors.<sup>477</sup> This is a pathologic process (*fibrinogenolysis*, pathologic proteolysis); it is discussed in Chapter 38. Fibrinolysis is thus regulated mainly by the levels of available plasminogen activators. Although plasminogen may be activated in the general circulation, the proteolytic action of plasmin is restricted to the site where it is homeostatically required, ie, in a fibrin mass. An alternative explanation for *in vivo* fibrinolysis is consistent with most of the available data, ie, plasmin forms inactive complexes with its inhibitors, which dissociate when they are adsorbed by fibrin.<sup>35</sup>

The *in vivo* activity of the fibrinolytic enzyme system is modified by several additional factors. Thus, diffusion of plasminogen activators into preformed thrombi may be relatively slow,<sup>376</sup> and fibrinolysis appears to be relatively slow in the general circulation. Such observations would suggest that this enzyme system plays only a minor role in lysing large thrombi in major vessels. However, when fibrin formation occurs in the presence of activator, activator is adsorbed and incorporated into the fibrin as it forms, and fibrinolysis may be very rapid. In intravascular coagulation, for example, massive amounts of fibrin may be lysed within a matter of minutes (Chapter 38). This phenomenon appears to be particularly important in the microcirculation, owing to the normal presence of high concentrations of activator. The action of factor XIII increases the resistance of fibrin to the proteolytic action of plasmin,<sup>171,201,291</sup> but the physiologic importance of this phenomenon is uncertain.

## Physiologic Variations

There is preliminary evidence that fibrinolysis follows a circadian rhythm, and is normally greater during the nocturnal hours.<sup>147</sup> Fibrinolysis also is more active in the elderly<sup>408</sup> and in females,<sup>91</sup> but is diminished in obese persons<sup>375</sup>; it is unaffected by the menses.<sup>84</sup> In pregnancy, fibrinolytic activity is subnormal at term, but rises rapidly to supernormal levels after delivery<sup>85,460</sup>; the levels of plasminogen closely parallel those of fibrinogen.<sup>81,219</sup> Anovulatory medications apparently do not significantly affect the fibrinolytic enzyme system.<sup>65</sup> A mild deficiency of plasminogen is present in normal neonates,<sup>52</sup> and in hypometabolic states<sup>51</sup>; high levels are present in hypermetabolism.<sup>54</sup>

## The Proteolytic Degradation of Fibrin: Degradation Products

The proteolytic action of plasmin on fibrin or fibrinogen leads to the formation of a family of soluble protein fragments (degradation or split products, FDP, FSP).<sup>265,517</sup> Intensive study of this process has provided convincing evidence that the sequence of events to be described below occurs physiologically, and proceeds in essentially the same manner whether *fibrinolysis* or *fibrinogenolysis* is involved. The major antigenic determinants of native fibrinogen are retained in fibrin and in the larger degradation products.<sup>315</sup> The immunologic methods usually used for the assay of these fragments do not distinguish between degradation products of various sizes, or between fibrin degradation products and those derived from fibrinogen.<sup>403a</sup> Consequently, throughout this book the abbreviation "FDP" will be used with reference to all of these substances.

The degradation of fibrin is a stepwise process (Fig. 10-8), and the molecular size of the resulting FDP thus varies with the duration of plasmin action. In the initial step, approximately 20% of the fibrinogen molecule is removed in the form of small peptides,

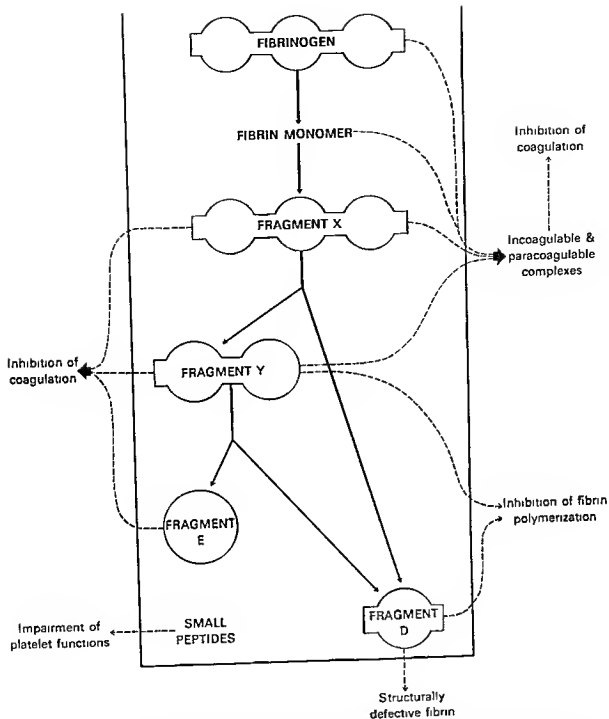

Fig 10-8. The proteolytic degradation of fibrinogen or fibrin the biologic effects of degradation products. The stepwise degradation of the fibrinogen or fibrin molecule by plasmin, essentially as viewed by Marder,<sup>315</sup> is indicated in the center block. Effects of various FDP on hemostatic functions are indicated by dashed lines. The symbols represent the trinodular model of fibrinogen structure, proposed by Hall and Slaytor.<sup>193</sup> The E fragments may represent the N-terminal disulfide knots.<sup>315</sup>

yielding *fragment X* (first derivative).<sup>151</sup> This fragment has a molecular weight of approximately 280,000, retains thrombin binding sites, and resembles but is not identical to<sup>333</sup> the soluble fibrinogen derivatives (fraction I-8) that normally are present in plasma.<sup>463</sup> The proteolysis of fragment X may yield a variety of large FDP, ranging in molecular weight from 100,000 to 200,000 (intermediate fragments)<sup>151,151</sup> Alternatively, this fragment may be split into one molecule of fragment D and one of fragment Y.<sup>315,317</sup> *Fragment Y* has an estimated molecular weight of 155,000. It is split into one molecule of fragment D and one of fragment E. The molecular weight of *fragment D* is approximately 90,000, while that of the smaller *fragment E* ranges from 30,000 to 50,000. There is preliminary evidence that fragment D is derived from the lateral nodules of the fibrinogen molecule (Fig 10-8), and that fragment E represents the "disulfide knot" of the central nodule (Fig. 10-1).<sup>315</sup> Both fragmented D and E are relatively resistant to further proteolysis by plasmin.

The larger fragments X and Y form soluble complexes with fibrinogen and fibrin monomer.<sup>462,474</sup> These complexes dissociate in the presence of alcohol and protamine sulfate to form gels and precipitates of various types, a phenomenon that has been termed *paracoagulation*.<sup>86,178,448</sup> Such complexes precipitate in the cold and in heparinized plasma (*cryofibrinogens*).<sup>340,341</sup>

### Biologic Effects of FDP

FDP and complexes thereof profoundly impair the hemostatic process, and are a major cause of hemorrhage in intravascular coagulation and fibrinolysis (Chapter 38). Extant assay methods determine only the total amount of FDP present, and evidence concerning the effects produced by each particular fragment is incomplete. Most FDP are inhibitors of coagulation, *fragment Y being the most potent in this respect.*<sup>152,466</sup> They are potent antithrombins (antithrombin VI), and also form incoagulable or slowly coagulating complexes with fibrin monomer or

fibrinogen. Poorly defined effects on other steps in coagulation have been demonstrated.<sup>357,506</sup> Fragments Y and D inhibit fibrin polymerization.<sup>21</sup> Fragment D, when incorporated into fibrin, produces a structurally defective fibrin polymer.<sup>151</sup> Purified fragment E is a potent inhibitor of thrombin.<sup>277</sup>

Various products of fibrinogen degradation impair platelet functions, but the details of this process are poorly understood (page 432).<sup>475</sup> Preliminary data would suggest that inhibition of ADP-induced platelet aggregation is due mainly to the effects of small dialyzable peptides.<sup>483,503</sup> Such small peptides also may be vasoactive.<sup>262</sup> Fibrin monomers and complexes thereof also may produce "hyperaggregability" of platelets, which may lead to in vivo clumping and sequestration.<sup>44,503</sup> "Paracoagulable" complexes also inhibit coagulation.<sup>262</sup>

FDP are removed from the circulation by clearance mechanisms in the liver and reticuloendothelial system.<sup>163</sup> The half-life of these fragments, as a group, is approximately nine hours.<sup>152</sup>

## Homeostatic Significance of Coagulation

### Hemostasis

Evidence obtained from in vitro experiments, as discussed above, suggests that the intrinsic and extrinsic pathways provide alternative methods of activating factor X. However, the presence of severe bleeding in patients with factor VII deficiency (Chapter 37) suggests that the extrinsic as well as the intrinsic pathway is essential for normal hemostasis. The physiologic role of the extrinsic pathway is, however, uniquely difficult to study. Animals with hereditary factor VII deficiency form hemostatic plugs normally, and do not provide a valid model since the canine disease is not associated with significant bleeding.<sup>227</sup> The major physiologic importance of the extrinsic pathway may lie in its ability to initiate the rapid evolution of

the first traces of thrombin and thus to initiate the autocatalytic phase of coagulation by activating factors V and VIII. Traces of thrombin also may further platelet aggregation (page 393) and lead to the formation of small amounts of fibrin.

Deficiency of factor XII (Hageman factor) is not associated with a significant hemorrhagic diathesis, despite the presence of gross abnormalities in various *in vitro* tests of blood coagulation (page 1179). This inconsistency would seem to raise serious questions concerning the physiologic importance of factor XII in the intrinsic pathway. Several ingenious experiments of questionable physiologic significance<sup>60</sup> suggest that, in factor XII deficiency, the intrinsic pathway may be activated by alternative mechanisms, ie, an interaction between factors VIII and IXa and substances derived from the platelets,<sup>45a</sup> or with the tissue factor-factor VII complex formed in the extrinsic pathway.<sup>60,63,365</sup> Such an alternate pathway could not activate factor X in the absence of factors VIII and IX, but could "bypass" factors XII and XI.<sup>60</sup> This hypothesis does not, however, explain why patients with factor XI deficiency bleed abnormally.<sup>369</sup>

The study of experimental wounds in animals with hereditary coagulation disorders<sup>227</sup> provides good evidence that the major hemostatic role of fibrin formation is to consolidate the temporary platelet thrombus, as discussed in Chapter 9. Thus, initial hemostasis was normal in factor IX-deficient dogs, but was delayed in factor VIII-deficient animals. In both groups, the hemostatic plug was deficient in fibrin and was loose and friable; re-bleeding was usually seen.<sup>227</sup> The observed differences between factor VIII- and factor IX-deficient animals remain unexplained, as does the fact that patients with hereditary afibrinogenemia do not bleed as severely as those with hemophilia A.

The unanswered questions discussed above emphasize an important axiom, ie, inferences drawn from the *in vitro* study of blood coagulation may have little, if anything, to do with the process as it occurs *in vivo*. The hemostatic role of coagulation may be even

more complex and much more subtle than is presently realized.

### The Question of Physiologic Intravascular Coagulation

It has long been theorized that the hemostatic process plays a continuous role of physiologic importance, in addition to its intermittent activity when vessels are injured. In terms of this hypothesis, platelets are continuously required for endothelial support, and a film of fibrin is continuously deposited on the endothelial surface of normal vessels, as a result of "physiologic intravascular coagulation,"<sup>107</sup> and is continuously removed by means of "physiologic fibrinolysis."<sup>1325</sup> This cycle is viewed as essential in maintaining normal vascular integrity, and the resulting utilization of platelets and coagulation factors is considered to be a major determinant of their *in vivo* catabolism.<sup>89,271,481</sup>

There is now considerable evidence against this hypothesis, however satisfying it may be teleologically.<sup>213</sup> The coagulation factors are catabolized more rapidly than other plasma proteins but available evidence would suggest that this is not a consequence of their continuous "physiologic consumption." Thus, the *in vivo* turnover rate of fibrinogen is unaffected by severe deficiencies of various coagulation factors, heparin and coumarin anticoagulants, or fibrinolytic enzyme inhibitors such as EACA,<sup>129</sup> all of which would be expected to retard cyclic intravascular coagulation and fibrinolysis. Studies of the effects of the above factors on vascular permeability or fragility have yielded largely inconclusive evidence. Electron microscopy has failed to demonstrate a fibrin film on normal endothelium, and the evidence for an "endothelial supporting function of platelets," discussed at length on page 399, remains unconvincing.<sup>213</sup>

The evidence cited above leads to the following conclusions: (1) coagulation and fibrinolysis are undoubtedly involved in the repair of numerous small or imperceptible vascular injuries that occur daily under normal circumstances; (2) even though this

process is essentially continuous, it does not appear to operate on normal uninjured endothelium; and (3) although small amounts of the various coagulation factors are undoubtedly utilized in this manner, there is no evidence that such "physiologic consumption" or "physiologic fibrinolysis" is a major factor in determining the *in vivo* catabolism of these proteins.

### Non-hemostatic Processes

Blood coagulation factors have been studied almost exclusively in terms of their role in hemostasis and in thrombosis (Chapter 39). Evidence suggesting that coagulation is involved in various other physiologic and pathologic processes is now accumulating.<sup>260,323,420</sup>

### Inflammation

Preliminary evidence would suggest that *factor XIIa* is required for the release of plasma kinins from their precursors in normal plasma,<sup>321</sup> and may activate the kinin system *in vivo*.<sup>369,424</sup> This factor also may be involved in the release of kinins from leukocytes,<sup>329</sup> and in the activation of C'1 esterase.<sup>124</sup> *Plasmin* activates both the kinin

system<sup>356,519</sup> and the early-reacting components of the complement system.<sup>280,399</sup> It also inactivates C'1 esterase inhibitor (page 333).<sup>186</sup>

The studies discussed above have led to the hypothesis that factor XIIa serves as a surface-sensitive "trigger mechanism" that translates the stimuli of injury into diverse homeostatic responses, i.e., hemostasis, immunologic and cellular defense, and repair (Fig. 10-9). However, there is no evidence that factor XII deficiency is associated with abnormal susceptibility to infection, and the role of this factor in inflammation, as in coagulation, remains a scientific curiosity. The activation of the kinin system by factor XIIa may be of pathophysiologic importance in gout, a disorder in which factor XII may be activated by sodium urate deposits in the synovia.<sup>254</sup>

### Wound Healing

Hereditary deficiencies of fibrinogen, factor XIII, and the dysfibrinogenemias (page 1174) are frequently associated with abnormal scar formation, wound dehiscence, post-circumcision bleeding, and bleeding from the umbilical stump. These findings are uncommon in other hereditary coagulation disorders, and have led to the hypothesis that optimal amounts of normal, stabilized fibrin

Fig 10-9. The diverse consequences of factor XII activation

are essential for normal wound healing.<sup>131</sup> There is some experimental support for this concept.<sup>51,266</sup> Thus, when fibroblasts are cultured in vitro in human plasma, fibrin appears to orient fibroblastic proliferation, a process that is grossly defective in factor XIII-deficient plasma.<sup>51</sup>

### Tumor Localization

The metastatic spread of neoplasms may depend on the presence or formation of fibrin at the site of lodgement of tumor emboli.<sup>493</sup> This has been attributed to elaboration of a coagulant substance by tumor cells.<sup>493</sup> Anti-coagulant drugs and agents that activate the fibrinolytic enzyme system appear to limit or retard neoplastic spread in some animal tumor systems,<sup>14</sup> but not in others.<sup>182</sup> Evidence concerning human tumors is equivocal.

#### **Blood Groups**

Blood groups represent systems of antigenic determinants found on the surface of red cells. These antigens are inherited according to simple mendelian laws and the major systems (eg, ABO and Rh-Hr) are inherited independently of each other.

Blood groups still are most readily identified by means of specific antibodies present in serum, either "naturally" or after immunization with foreign red cells or soluble blood group substances. The chemical characterization of blood group antigens has lagged far behind serologic and genetic studies and so far only the ABO, Lewis, and, to a lesser extent, the *Ii* and *MN* systems have lent themselves to extensive biochemical analysis. The study of the ABO and Lewis systems has been greatly facilitated by the discovery that the antigens in question occur not only as surface components of cells, but also are found in water-soluble form in the tissue fluids and secretions of most people.

#### **The ABO and Lewis Systems**

At the turn of the century, Landsteiner first described the existence of serologic differences between individuals<sup>38</sup> allowing him to classify people into one of four groups, depending on whether their red cells contained "agglutinin" A, "agglutinin" B, neither A nor B (O), or both A and B (AB). This

Table 11-1. The ABO Blood Groups

Phenotype (Group)	Genotype	Antigens on Red Cells	Antibodies in Serum
O	OO	None	Anti A Anti B
A	{ AA AO	A	Anti-B
B	{ BB BO	B	Anti-A
AB	AB	A and B	None

discovery led to a series of serologic, genetic, and immunochemical studies that are continuing even at the present time.

**ABO ANTIGENS.**<sup>52,56</sup> The ABO antigens are inherited as simple mendelian characters, the blood group of an individual depending on the presence of two out of three allelic genes: A, B, and O. The possible genotypic and corresponding phenotypic combinations are listed in Table 11-1. The antibodies reacting with the A or B antigen are regularly found in the serum when the corresponding antigen is absent from the red cells. These antibodies were originally thought to occur spontaneously but are now known to arise early in life as a result of exposure to ABO-like polysaccharides that occur ubiquitously in microorganisms, food, and other exogenous sources.

In addition to antibodies against A and B antigens, reagents reacting preferentially with O cells are known. The antigen defined by these reagents is known as H substance and its synthesis is under the control of an allelic pair of genes, H-b, inherited independently of the ABO system. Indeed, since there is no "true" O antigen, group O individuals would be more precisely identified as group H individuals; however, the group O designation is retained for historical reasons.

The H gene in single or double dose gives rise to the H character, and the rare h allele, when present in double dose, results in the absence of the H character. The H-active material appears to be a precursor substance which, under the influence of A and B genes,

is converted into A and B active substances, respectively, thereby accounting for the presence of large quantities of H substance in O individuals. It also follows that the rare hh individuals, termed the "Bombay phenotype,"<sup>56</sup> lack A, B, or H antigens on their erythrocytes and in secretions (Table 11-2). Nevertheless they appear to have normal A and B genes that can be expressed in the next generation if their children acquire an H gene from the other parent.<sup>4,41</sup>

Approximately 80% of northern Europeans with A, B, or H antigens on their red cells also have the corresponding antigen in various tissue fluids and secretions. While the A, B, and H antigens on red cells are predominantly glycolipids (see below), their soluble counterparts in secretions are glycoproteins. The capacity to secrete these substances is under the control of a pair of allelic genes, Se-se. Se is considered dominant over se, and only homozygous sese individuals are therefore "nonsecretors" of A, B, or H substances. Among secretors, the concentration of A, B, and H substances in secretions is influenced by the ABO type of the individual.<sup>79</sup>

**THE LEWIS SYSTEM.** Systematic work on the Lewis system stemmed from the discovery of anti-Le<sup>a</sup> by Mourant in 1946 and anti-Le<sup>b</sup> by Andresen in 1948.<sup>58</sup> Landsteiner and Levine,<sup>39</sup> however, probably first described an example of anti-Le<sup>a</sup>. The Lewis system is closely related to the ABO system, although the two allelic genes, Le and le, which define this system, are inherited independently of the ABO, Hh, and Sese genes.<sup>50</sup> In single or double dose, Le gives rise to the Le<sup>a</sup> specific structure; le in double dose results in its absence. Le<sup>b</sup> specificity, once thought to arise from the activity of an allele of the Le gene, is now considered to be an interaction product between the H and Le genes. Thus, three Lewis red cell phenotypes are possible; these are designated Le(a+b-) or Le<sup>a</sup>, Le(a-b-), and Le(a-b+) or Le<sup>b</sup>.

The Le<sup>a</sup> and Le<sup>b</sup> antigens, unlike their ABH counterparts, are not integral parts of the red cell membrane, but, instead, are acquired from the plasma.<sup>52</sup> Since the secretion

of Le<sup>a</sup> substance is *not* under the control of the Sese gene;<sup>68</sup> nonsecretors have Le<sup>a</sup> antigens on their red cells and in their secretions as long as the Le gene is present. However, since the secretion of H gene products is under the control of the Sese genes, the Le<sup>b</sup> antigen, which is an interaction product between the H gene and the Le gene, is only found in the secretions and on the red cells of secretors (Table 11-2). Thus, the H, Le, and Se genes are *all* required to produce the Le(a-b+) phenotype.

Lewis-negative erythrocytes are readily converted to Le(a+b-) or Le(a-b+) erythrocytes by incubation with the appropriate plasma *in vitro*.<sup>53</sup> Most of the plasma and erythrocyte Lewis antigens appear to be glycosphingolipids and not glycoproteins.<sup>27,53</sup>

Some serious transfusion reactions<sup>56</sup> and a few instances of hemolytic disease due to anti-Lewis antibodies<sup>49</sup> have been reported.

A postulated pathway for the biosynthesis of ABH and Lewis antigens is shown in Figure 11-1.

### Immunochemistry

The chemical composition of *secreted* ABH and of Lewis substances is remarkably similar. Both are composed of a carbohydrate moiety that constitutes about 85% of the molecule and an amino acid moiety that

makes up the remaining 15%.<sup>32,66,66</sup> They are heterodisperse, with an average molecular weight of 300,000,<sup>35,65,66</sup> but the molecules of different sizes have similar composition and molecular properties. The peptide residues are always composed of the same 15 amino acids, and four of these—threonine, serine, proline, and alanine—make up two thirds of all the amino acids present.<sup>12,66</sup> The peptides appear to have structural functions *only* and are thought to form a firm, spiny backbone to which a large number of relatively short oligosaccharide chains, constituting the blood group substances, are attached at intervals.<sup>33,52,66</sup> The carbohydrate moiety of all the ABH and Lewis substances is qualitatively similar in composition.<sup>42</sup> Each contains a methyl-pentose, L-fucose; a hexose, D-galactose; two amino sugars, N-acetyl-D-glucosamine and N-acetyl-D-galactosamine; and a 9-carbon sugar, N-acetyl neuraminic acid. One of these sugars appears to be immunodominant in each of the blood group substances studied.

Cellular blood group substances are much more difficult to isolate, but both A and B active materials have been obtained in water-soluble form. In contrast to the blood group substances found in secretions, most of the cell-derived extracts are glycolipids,<sup>27,83</sup> although some glycoprotein residues have been found as well.<sup>30</sup> Nevertheless, it

Table 11-2. Relation between Genotype, Erythrocyte Phenotype, and Antigenic Specificities Detectable in Secretions

Probable Gene Combination	Antigens Detectable on Red Cells			Specificities Detectable in Secretions

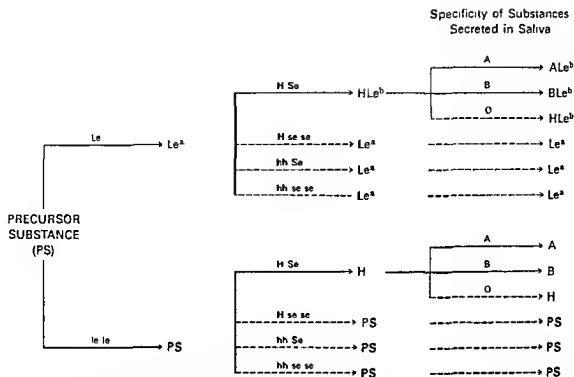

Fig. 11-1 Hypothetical pathway for the biosynthesis of the ABH and Lewis antigenic determinants in glycoproteins under the control of the Le, H, Se and ABO genes. A solid arrow indicates that a sugar residue was added to the glycoprotein, and a broken arrow that no sugar was added. (From Marcus,<sup>52</sup> courtesy of the author and New England Journal of Medicine.)

appears that the oligosaccharide chains that confer blood group specificity on the glycolipid blood group substances of red cells, as well as the glycoprotein substances found in secretions, are identical,<sup>27, 54, 88</sup> thereby accounting for the similarities in the specificity of antigenic determinants on red cells and in secretions.

The complicated interrelationship between A, B, H, and Lewis substances was clarified considerably when it was recognized that the gene systems controlling these four expressions appear to act sequentially on a common glycoprotein precursor substance.<sup>45, 86</sup> Genetic control presumably comes about through the formation of specific glycosyl transferase enzymes or through some mechanism controlling their function. A simplified version of such a proposed scheme is illustrated in Figure 11-2.

Two precursor chains are recognized on the basis of a  $1 \rightarrow 3$  (type 1) or  $1 \rightarrow 4$  (type

2) linkage of the terminal galactosyl unit to the subterminal N-acetyl glucosamine residue.<sup>86</sup> The latter precursor chain has cross-reactivity with antisera to type XIV pneumococcal polysaccharide.<sup>3</sup>

The transferase controlled by the H gene is thought to add L-fucose in  $\alpha$ -linkage to the carbon 2 position of either chain to form an H-active structure.<sup>43, 44</sup> The enzyme controlled by the Le gene, also a fucosyl transferase, adds L-fucose in  $\alpha$ -linkage to the 4 position of the subterminal N-acetylglucosamine unit in chains of type 1 only, as chains of type 2 already are substituted at this position. The resultant structure has  $Le^a$  specificity.<sup>45, 70</sup> Nevertheless, a type 2 oligosaccharide containing fucose linked to C-3 of N-acetylglucosamine may also have very weak  $Le^a$  activity.<sup>45</sup> When both H and Le genes are present, two fucosyl units are added to adjacent sugars on chains of type 1, resulting in a structure which, on the basis of in-

hibition experiments, is thought to be that of the  $\text{Le}^b$  determinant.<sup>55</sup> Type 2 difucosyl chains have weak  $\text{Le}^b$  activity.<sup>55</sup>

The presence of the fucosyl unit conferring H specificity to the precursor substance is considered to be essential for the functioning of the transferases controlled by the A and B genes. Thus, N-acetyl-D-galactosamine added in  $\alpha$ -linkage to carbon 3 of the terminal galactosyl unit confers A-specificity to the H-active precursor substance,<sup>45,70</sup> whereas addition of D-galactose in identical linkage results in B specificity.<sup>43,41</sup> The addition of these terminal nonreducing sugars effectively masks the serologic reactivity of the H-active groupings, and the  $\text{Le}^a$ -active determinants are similarly masked by the substitutions controlled by the H gene. The  $\text{Le}^b$  substance, however, is usually found in good concentration on the red cells and in the secretions of A, B, or AB subjects.<sup>68</sup>

Among individuals who possess the A antigen, two main subclasses have been identified. Subgroup  $A_1$  includes about 80% of Europeans,<sup>56</sup> whereas the remainder belong to subgroup  $A_2$ . Similarly, 80% of AB samples are  $A_1B$ , whereas 20% are  $A_2B$ .  $A_1$  and  $A_1B$  individuals do not form anti- $A_2$  antibodies, but a small proportion of  $A_2$  individuals (1%) and a larger proportion of  $A_2B$  individuals (25%) form anti- $A_1$  antibodies.

The basis for the difference between  $A_1$  and  $A_2$  specificity has been in dispute from the moment of its discovery.<sup>57</sup> One view holds that the  $A_1$  and  $A_2$  antigenic determinants are chemically identical, but that  $A_1$  individuals simply have many more determinants on their red cells than do  $A_2$  individuals.<sup>5,51,57</sup> The other view maintains that there is a qualitative difference between the antigenic determinants of  $A_1$  and  $A_2$  individuals,<sup>27,57</sup> and it has been suggested, on the

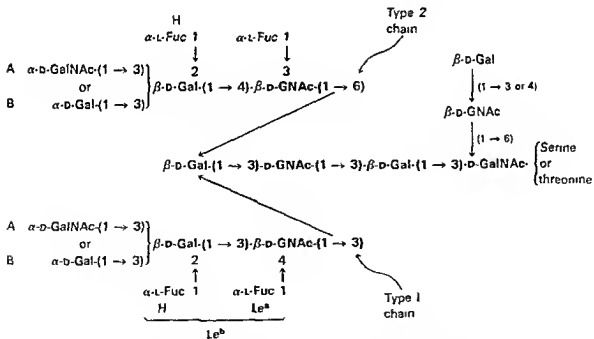

Fig. 11-2 Proposed composite structure of A, B, H,  $\text{Le}^a$  and  $\text{Le}^b$  specific blood group substances linked to serine or threonine spines of the polypeptide backbone. Gal refers to galactose, Fuc to fucose, GNAc to N-acetylglucosamine, GalNAc to N-acetylgalactosamine. The numerical notations (eg 1  $\rightarrow$  4) refer to the respective carbon positions at which linkage occurs. The precursor substance is identified by bold type. The determinants characteristic of a given blood group substance are in light type and are identified by their appropriate symbols, namely A, B, H,  $\text{Le}^a$ , and  $\text{Le}^b$ . The structure shown is a composite which includes all determinants. In individual blood group substances certain residues will be missing: eg H,  $\text{Le}^a$ , and  $\text{Le}^b$  specific blood group substances lack A and B specific determinants, and  $\text{Le}^a$  substance also lacks the H specific determinant. See text and references for details. (From Lloyd et al.,<sup>45</sup> courtesy of the authors and Biochemistry)

basis of immunochemical studies, that  $A_2$  substances lack Type 1 A-determinants<sup>57</sup> (see Fig. 11-2), whereas  $A_1$  substances contain both Type 1 and Type 2 A-determinants.<sup>57</sup> This would also account for the observed higher H and  $Le^b$  activity in  $A_2$  substances, since the addition of the terminal sugar conferring A reactivity ordinarily masks the H or  $Le^b$  active determinants on the precursor chain. Definite proof of molecular differences between  $A_1$  and  $A_2$  determinants will have to await the isolation and structural analysis of  $A_2$  substances.

Numerous variants of  $A_2$  that can be characterized by a variety of serologic techniques have been described.  $A_{31}$ , for instance, is thought to be a "weaker" form of  $A_2$ .<sup>56,71</sup> and even "weaker" forms ( $A_1$ ,  $A_{31}$ ,  $A_m$ ) have been reported.<sup>56-58</sup> These variants are very rare, but may on occasion cause difficulty during typing or cross-matching procedures. The structural basis for these lesser variants, if indeed this is the cause of their poor performance as A antigens, is completely unknown.

While variants of A are encountered with some frequency, variants of B are most uncommon.<sup>18,56,68,89</sup> Occasionally weak B-like antigens have been acquired in association with various diseases, especially malignant ones.<sup>11,23</sup>

**SEROLOGIC SPECIFICITY C.** The classic description of the ABO system and its corresponding isoantibodies (Table 11-1) does not explain a number of puzzling serologic observations.<sup>92</sup> (1) When group O serum is absorbed with A cells, the anti-B titer is lowered as well, and when group O serum is absorbed with B cells, the anti-A titer is decreased also. This phenomenon is not observed when simple mixtures of anti-A and anti-B sera are similarly absorbed. (2) Injection of A cells into O individuals may result in an increased titer of anti-B in addition to the expected rise in anti-A, and vice versa. (3) Eluates of group O serum from group A cells may also agglutinate group B cells, and eluates from B cells may agglutinate A cells.

According to Wiener and associates,<sup>76,92</sup>

group O serum contains, in addition to anti-A and anti-B, antibodies of a third type that react with the blood factor C. In nonimmunized group O subjects the titer of anti-C is generally quite low, but rises sharply following immunization with A or B cells.<sup>92</sup> C factor is present on all red cells having A or B specificity and is also found on the red cells of rare individuals who react with anti-C, though lacking both A and B. When sera containing potent anti-C are absorbed with such "group C" cells, the anti-C activity is removed while anti-A and anti-B activities remain.<sup>92</sup> Absorption with A or B cells, on the other hand, removes the anti-C activity as well.<sup>92</sup> The biochemical structure of the C specificity is unknown.

According to others, Wiener's anti-C, which they term anti-AB, simply reacts with cross-reacting structures common to A and B.<sup>56</sup> These workers have been unwilling to assign a separate specificity to these antisera. Wiener and coworkers consider anti-C to be important in ABO hemolytic disease of the newborn<sup>76</sup> whereas others do not.<sup>94</sup>

### *Distribution of ABH and Lewis Substances*

ABH substances have been found on cells other than erythrocytes. They are found in membranes of all vascular endothelial cells<sup>84</sup> and in many stratified and pseudostratified epithelia, including those of the skin, tongue, esophagus, uterine cervix, and lower genitourinary tract.<sup>84</sup> In addition, blood group substances have been found in the collecting tubules and calyces of secretors,<sup>80</sup> but it is not clear whether they are synthesized by the kidney or merely excreted. When human cell lines possessing ABH antigens are grown in tissue culture, the A and B antigens usually are lost, but the H specificity is retained.<sup>20</sup>

The presence of ABH and Lewis substances in secretions has been mentioned previously. The secretor (Se) gene controls the content of ABH substances in most secretions, including those of the salivary glands, the upper respiratory tract, and the superficial glands of the entire intestinal tract, including

those of the stomach and small intestine. In addition, individuals with the Se gene also have ABH substances in the secretions of the uterine cervix, the prostate, and the lactating mammary gland.<sup>80,84</sup> The mammary gland is of special interest since abundant H substance, but much less A substance and virtually no B substance, is produced by secretors of all ABH phenotypes.<sup>17</sup>

Glands situated more deeply in the mucosa of the pylorus and small intestine, such as Brunner's glands, produce A and B substances in secretors and nonsecretors alike.<sup>25,80</sup> The same is true for gastric parietal glands,<sup>81</sup> the exocrine acini of the pancreas, and the secretory coils of the sweat glands.<sup>89</sup>

Blood group A and B glycoproteins have been isolated from the urine,<sup>34,47</sup> but it is not clear whether they are secreted or simply derived from membrane associated antigens.

### ***Ontogeny of ABH Blood Group Substances***<sup>52,83,85</sup>

ABH substances have been detected as early as the fifth week of embryonal life, when they are found on all vascular endothelia and all epithelia except those of the nervous system, the adrenal gland, and the liver. As differentiation occurs, the antigens progressively disappear, and achieve an adult distribution at the end of the third intrauterine month. Soluble ABH and Lewis substances first appear in the secretions of the salivary glands and the stomach at the end of the second intrauterine month.

### ***ABO Blood Groups and Human Disease***

*Blood transfusion reactions* are discussed later in this chapter. ABO *hemolytic disease of the newborn* is described in Chapter 27.

ABO antigens are known to act as potent *transplantation antigens* in man. It has been found, for instance, that hyperimmunization with incompatible ABO antigens will result in accelerated skin-graft rejection when the donor is incompatible for the same ABO antigen,<sup>36,69</sup> whereas skin grafts from ABO

compatible individuals are accorded survival times characteristic of first grafts in non-sensitized individuals. It has also been found inadvisable to use donor kidneys containing A or B antigens lacking in the recipient.<sup>24</sup> In one study, 46% of kidney transplants with ABO incompatibility failed to show initial function, as compared to only 9% in ABO compatible pairs.<sup>24</sup>

For several decades the ABO groups have been suspected of contributing to *infertility and fetal loss*, but the reports have been conflicting and often speculative. Cumulative evidence now indicates that ABO incompatibility between mother and fetus results in a small but significant decrease in fertility,<sup>40</sup> which may be due to prezygotic selection, prevention of fertilization, or fetal death.<sup>52</sup>

Prevention of fertilization would presumably occur through damage to ABO incompatible sperm by isoantibodies of the cervical secretions.<sup>5,22</sup> About two thirds of all women have these kinds of isoantibodies in their cervical secretions, which are usually IgG and may be produced locally.<sup>64,75,77</sup> The ABO antigens of sperm appear to be acquired from the seminal secretions and are only found on the sperm of secretors.<sup>9,19</sup>

The increased incidence of fetal deaths is usually attributed to fetal damage by maternal IgG antibodies that cross the placenta.

*Alterations in red cell phenotypes* have been observed in a variety of malignant conditions. Loss or suppression of the A<sub>1</sub> antigen has been noted in leukemia.<sup>28,68,71,78</sup> The change is usually confined to red cells and is accompanied by increased H-activity. The loss of the B antigen of an A<sub>1</sub>B patient also has been reported.<sup>72</sup> The acquisition of B-like antigens by patients with malignant disease or infections<sup>23,68</sup> has been mentioned already.

Supposedly significant departures from expected ABO frequencies have been observed in patients with various kinds of disorders. Thus, group A individuals have been reported to be more susceptible to gallstones,<sup>35</sup> cirrhosis of the liver,<sup>7</sup> and tumors of the salivary glands,<sup>61</sup> stomach,<sup>29</sup> and pancreas,<sup>1</sup> as well as ovary<sup>63</sup> than are members of the other groups. In addition, duodenal ulcera-

tion was found to be more common in non-secretors than in secretors of blood group antigens and especially in group O individuals.<sup>13</sup> An increased incidence of myocardial infarction<sup>2</sup> and diabetes mellitus<sup>50</sup> has also been reported in group A individuals. The significance of these studies has been questioned by Wiener and others.<sup>91</sup>

### The Ii System

The red cells of almost all healthy adults carry an antigen I<sup>113,115</sup> and smaller amounts of a related antigen, i.<sup>109</sup> Very rare individuals, perhaps one in 10,000, have little or no I antigen, but they usually have anti-I in their serum.<sup>109</sup> All newborns appear to have the phenotype i since they react strongly with anti-i and weakly with anti-I.<sup>109</sup> It is possible, however, that cord cells may contain I-antigen in a cryptic form since it is possible to isolate I-positive material from such cells.<sup>112</sup> During the first 18 months of life the cells gradually change to the I phenotype and in healthy individuals this reaction pattern appears to be retained throughout life.<sup>109</sup>

Water-soluble I blood group substance has been demonstrated in human saliva, milk, amniotic fluid, and urine.<sup>97,100,110</sup> It has also been found in the saliva of young infants and in the saliva and milk of i-adults who lack the I antigen on their red cells.<sup>99,110</sup> These individuals may nevertheless have potent anti-I in their sera.<sup>110</sup>

In patients with a variety of hematologic disorders, i activity of the red cells may increase again, usually without a demonstrable decrease in I activity. This is particularly true in situations of marrow stress,<sup>105</sup> such as occur in thalassemia major<sup>104</sup> or chronic hemolytic anemia, but it may also be found in hypoplastic anemia<sup>101</sup> and leukemia.<sup>104,108</sup> In the last instance, the i-reactivity of red cells may disappear when the patient achieves a remission.

A relationship between the ABO and Ii systems has been suspected for many years because the red cells of some Oi individuals were found to react very weakly with anti-H sera<sup>113</sup> and because cells of the Bombay phenotype (page 452) usually give a higher

score with anti-I than do ordinary Oi cells.<sup>56</sup> Immunochemical studies with various blood group substances have now confirmed the earlier suspicion.<sup>99,101,102</sup> A complex family of I antigenic determinants has been found in presumed precursors of A, B, H, Le<sup>a</sup>, and Le<sup>b</sup> substances derived from milk, ovarian cyst fluid, and bovine blood group substances. In addition, the careful stepwise degradation of A and B substances yields precursor-like materials with increased I activity. It has therefore been suggested that I specificity appears at intermediate stages in the biosynthesis of A, B, H, Le<sup>a</sup>, and Le<sup>b</sup> substances and that the enzyme produced by the I gene must act on a common precursor just prior to the steps controlled by the A, B, H, and Le<sup>a</sup> genes.<sup>102</sup>

Anti-I antibodies were first described as potent cold agglutinins in the serum of a patient with acquired hemolytic anemia.<sup>115</sup> Anti-I is also found as a weak cold agglutinin in the serum of normal individuals,<sup>56,113</sup> in the serum of most I-negative adults,<sup>113</sup> in patients with certain infections, especially mycoplasma pneumonia, and in patients with idiopathic cold agglutinin disease (Chapter 27). Anti-i is found in patients with malignant disease (Chapter 53) and in association with some infections, especially infectious mononucleosis (Chapter 43), but Wiener could not confirm this last finding.<sup>114</sup>

Anti-I and anti-i sera from various sources have been shown to be distinctly different in specificity as revealed by their reaction patterns against a variety of blood group substances and their precursors,<sup>99,101</sup> pointing to the extraordinary complexity of the I system. One anti-I serum was shown to have maximal specificity for the terminal nonreducing  $\beta$ -D-Gal-(1  $\rightarrow$  4)- $\beta$ -D-GNAc-(1  $\rightarrow$  6) structure present in the type 2 precursor substance (Fig. 11-2). The determinants involved in other I specificities have not been established.<sup>99</sup>

### The Rh System

In 1939 Levine and Stetson published the report of a fascinating observation:<sup>124</sup> the mother of a stillborn baby had a severe

hemolytic reaction to her husband's blood and her serum agglutinated not only her husband's red cells, but also those of 80 out of 104 ABO compatible individuals. The authors correctly suggested that the mother had become sensitized to a "new" antigen, which she lacked herself, but which her stillborn baby had inherited from the father. One year later, Landsteiner and Wiener reported their surprising discovery that the sera of rabbits and guinea pigs immunized with the red cells of Rhesus monkeys agglutinated not only the monkey erythrocytes, but also those of most Caucasian New Yorkers.<sup>123</sup> Individuals whose red cells were agglutinated by these sera were termed "Rh-positive," the others "Rh-negative." These observations suggested the presence of a new system of red cell antigens and stimulated immediate inquiry into the nature of previously unexplained intragroup transfusion reactions and the incompatibilities between mother and child that cause erythroblastosis fetalis (Chapter 27). It was soon demonstrated that most of these reactions could be accounted for by antibodies resembling those described by Landsteiner and Wiener.<sup>136</sup>

From this modest but auspicious beginning has evolved the most complex of human blood group systems, currently characterized by over 30 antigens and antibodies and an almost unlimited number of apparently complex alleles.

Two systems of nomenclature are still in common use and therefore both need to be considered. According to Fisher<sup>127</sup> the inheritance of Rh antigens is determined by three pairs of closely linked allelic genes: Cc, Dd, Ee. Each parent would contribute three genes—C or c, D or d, E or e—each defining a single antigen. Since every person carries a chromosome from each parent, various combinations of genotypes would be found. A person might therefore inherit CDe from one parent and cde from another (CDe/cde), or he may be CDe/CDc, cde/cde, cDe/cde, or CDe/cDe, to mention only some of the most common types. However, so far the postulated anti-d has not been found.<sup>68</sup>

Fisher's theory also assumes that crossover of linked genes can take place, thereby ac-

counting for the maintenance of the rarer combinations by occasional crossing over from common heterozygotes, but there is no convincing evidence to support this suggestion. Moreover, intermediate forms and other variants that do not fit into Fisher's scheme are being discovered; these will be discussed later (page 460).

Wiener's system of nomenclature, which antedates that of Fisher, is based on a different genetic theory, according to which the inheritance of Rh antigens is determined by a series of allelic genes at one locus.<sup>137,138</sup> This means that the inheritance of Rh antigens is determined by a single gene, rather than three separate ones, as postulated by Fisher. This theory now is considered to be correct.<sup>36</sup>

In order to understand Wiener's nomenclature, two terms need to be explained. The term "agglutnogen" is used to describe the whole antigen complex determined by a given gene. Unfortunately its structure and physicochemical properties are not yet known, but it can nevertheless be identified by its "blood factors," the serologic specificities defined by antibodies directed against various facets of its structure. According to Wiener, the terms "blood factor" and "antigenic determinant" are not synonymous, since one and the same antigenic determinants may be identified by different families of antibodies in slightly different ways,<sup>138,139</sup> just as one blind person might identify a face by its nose, while another identifies the same face by its nose and its mouth, and yet another by its mouth and its ears. In his own publications, Wiener uses italics for gene symbols and genotypes, regular type for agglutinogens and phenotypes, and boldface type for blood factors and their corresponding antibodies (not shown in Table 11-4). In addition, the letter h is omitted from gene symbols and only superscripts are used.

An example will help to illustrate the difference between the Wiener and Fisher-Race terminologies. According to Wiener, a single gene R<sup>2</sup> determines the "agglutnogen" Rh<sub>2</sub> (cDE), which may be identified by its corresponding "blood factors" Rh<sub>0</sub> (D), rh"

(E), and hr' (c). According to the Fisher-Race system, the phenotype cDE is the result of three closely linked genes, c, D, and E, that an individual has inherited from one of his parents. One of the drawbacks of the Wiener terminology is its apparent complexity. In addition, one cannot deduce the nature of constituent blood factors from the notation for a given agglutinin. The factors have to be memorized. On the other hand, the Fisher-Race terminology is deceptively simple, implying, for instance, that cDE contains only c, D, and E, whereas it may in fact contain other "blood factors" as well.

The most important blood factors of Wiener and their corresponding Fisher-Race notations as well as the approximate frequencies of the various blood factors in Caucasians are given in Table 11-3. Wiener's gene designations, corresponding agglutinogens, and blood factors, as well as the corresponding Fisher-Race notations are given in Table 11-4.

The observed blood type of each individual is the product of a pair of genes. When the eight genes listed in Table 11-4 (Wiener's notation) are paired with each other, 36 genotypes are possible. The number of observed phenotypes is considerably less, however, since in each combination a factor may be represented once or twice, or two different

factors may be on the same or on different agglutinogens, without changing the phenotype. Thus, using the six antisera listed in Table 11-5, 20 Rh-Hr "phenotypes" can presently be identified.

In addition to the 6 Rh-Hr factors listed in Table 11-5, an ever expanding number of rare variants continues to add complexity to the Rh-Hr system. These include: (1) alternatives to common factors (allelic antigens); (2) compound antigens or, according to the Fisher-Race interpretation, joint products of theoretically separable genes; (3) deletions or suppression of some Rh antigens; (4) Rh null; (5) the LW antigen.

**ALLELIC ANTIGENS.** These variants appear to function as cognates for one of the more common factors. Thus  $rh^{W1}(C^W)$  and  $rh^X(C^X)$  appear to be associated with  $rh'(C)$ ,  $rh^{W2}(E^W)$  appears to be associated with  $rh''(E)$ , and  $D^U$  and  $D^W$  substitute for D. In addition,  $Rh_0(D)$  and  $rh''(E)$  cognates with missing components have been described.

$rh^{W1}(C^W)$  occurs in 2% of Caucasians, but in certain northern European population groups, such as Latvians, Finns, and Lapps, incidence rates as high as 7 to 9% are found.<sup>68</sup>  $rh'(C)$  individuals may make antibodies against the  $rh^{W1}(C^W)$  factor. In contrast, the  $rh^X(C^X)$  variant is rare (0.03% in Caucasians). Apparently the corresponding antibody may occur in individuals suffering from acquired hemolytic anemia.<sup>68</sup>

$Rh_0(D^U)$  appears to be the product of variant  $R^0$  genes, which result in a series of rather "weak"  $Rh_0(D)$  antigens. Alternatively it has been suggested that some of these "weak" antigens may be due to a position effect exerted by  $rh'$  on the ordinary  $Rh_0$  in the opposite gene complex, as in the genotype  $R^0r'$ .<sup>119</sup> Gradations of reactivity with anti  $Rh_0(D)$  sera have been reported; while the cells of some  $Rh_0(D^U)$  individuals are agglutinated by certain antisera only, the cells of others are not, and are serologically indistinguishable from  $r'r$  ( $Cdc/cdc$ ) or  $r'r$  ( $cDE/cde$ ) cells,<sup>68</sup> except by a positive indirect anti-globulin response with incomplete anti-D sera.<sup>68</sup> The antigen is of practical importance

Table 11-3. Wiener<sup>138</sup> and Fisher-Race<sup>68</sup> Rh Terminology

Rh Hr Blood Factors	CDE Terms	Approximate Frequencies of Blood Factors in Caucasians (%)
$Rh_0$	D	85
$rh'$	C	70
$rh''$	E	30

Wiener, in his publications uses italics for gene symbols and for genotypes regular type for agglutinogens and phenotypes, and bold faced type for symbols for blood factors and for the corresponding antibodies used to detect the blood factors in question. Further, to distinguish the symbols for genotypes and phenotypes, the letter 'h' is omitted and only superscripts are used in gene symbols.

because  $Rh_0(D^U)$  is common in Negroes, because it can stimulate anti- $Rh_0(D)$  antibodies in type *rh* individuals and because some  $Rh_0(D^U)$  individuals have made anti- $Rh_0(D)$  antibodies.<sup>63</sup>

Variants of  $Rh_0$  with increased reactivity have been reported in rare instances and will

be discussed in a subsequent section (page 462).

**OTHER COGNATES OF  $Rh_0$  FACTORS.** It has been known for some time that a few  $Rh_0(D)$  individuals can make antibodies simulating anti  $Rh_0(D)$  in specificity.<sup>123</sup> It has been

postulated that these individuals lack some part of the normal  $Rh_0$  factor and make antibodies to this missing part. Wiener suggested that the  $Rh_0$  factor may have associated with it a series of factors,  $Rh^A$ ,  $Rh^B$ ,  $Rh^C$ ,  $Rh^D$ . He indicates missing specificities by a small letter, for instance,  $Rh^c$ ,  $Rh^{c'}$ , etc.<sup>135</sup> It has been found that typically reacting  $Rh_0$  samples in blacks and whites seldom lack constituent components; however, about half of the  $Rh_0(D^U)$  bloods tested lack one or more of the cognate factors.<sup>135</sup>

The specificity  $E^T$  appears to be missing from the  $rh''(E)$  antigen of about one third of Australian aborigines living in the Western Desert.<sup>68</sup> An anti- $E^T$  antibody, apparently naturally occurring, was found in the serum of an Australian aborigine of the genotype  $R^1R^2(CDe/CDe)$ .

**COMPOUND ANTIGENS.** These are produced when two standard factors, both situated on the same agglutinin, combine determinants to give rise to a new specificity. The original factors,  $hr'$  (c) and  $hr''$  (e), have to be in the "cis-position" with respect to their agglutinin. (Cis-position simply indicates that the blood factors are products of the same gene and are therefore situated on the same agglutinin. Similarly, factors situated on different agglutinins and derived from opposing chromosomes are said to be in the "trans-position.") The resulting factor  $hr$  (ce) gives rise to antibodies that do not react with  $hr'$  (c) or  $hr''$  (e) separately. This compound factor has previously been referred to as anti-f or anti-Ce.<sup>120,128</sup>

Other "compound" antigens may include  $rh_1(Ce)$ ,  $rh_2(cE)$ ,  $rh_2(CE)$  and, perhaps, several others.<sup>68</sup>

**SUPPRESSIONS.** There are rare but theoretically important agglutinogens with part or all of their factors missing. Thus the genetically determined agglutinin  $Rh_0(D-)$  lacks factors at both the  $rh'-hr'$  (Cc) and  $rh''-hr''$  (Ee) positions and has instead greatly increased  $Rh_0(D)$  activity.<sup>68</sup> The  $Rh_{null}$  phenotype may represent an extreme example of this type of suppression (see below). Other rare examples of suppression have been summarized by Race and Sanger.<sup>68</sup>

$Rh_{null}$ .<sup>122,126,131</sup> This is a most unusual blood type that lacks all Rh-Hr factors. In addition, aberrations of the MNSsU system have been reported.<sup>131</sup> Two types of  $Rh_{null}$  have been postulated. One is thought to result from the effect of a suppressor gene (z), when the person is homozygous for that gene.<sup>126</sup> Thus an  $R'r$  zz individual would react as  $Rh_{null}$  and his blood is designated  $\bar{r}h$ . Alternatively,  $Rh_{null}$  could be the result of homozygosity for an allelic gene  $\bar{r}$ . This would result in the genotype  $\bar{r}\bar{r}$  and the blood would be designated  $\bar{r}h$ .<sup>122</sup> Others consider  $Rh_{null}$  to be the result of gene deletions.<sup>131</sup>

$Rh_{null}$  individuals are of added interest to hematologists, since they suffer from chronic hemolytic anemia characterized by spherocytosis, stomatocytosis, "smiling erythrocytes," and increased osmotic fragility.<sup>132</sup> No intracorpuscular or other membrane defects have so far been demonstrated.

The anti-Rh antibodies are described in Chapter 27.

**THE LW ANTIGEN.** In 1940, Landsteiner and Wiener discovered that the sera of rabbits and guinea pigs immunized with the red cells of Rhesus monkeys also agglutinated the erythrocytes of most Caucasian New Yorkers (see above). According to Wiener this antibody reacts with antigens presently known to be part of the Rh system,<sup>140</sup> but others claim that it reacts with a different antigen, LW (named in honor of Landsteiner and Wiener<sup>125</sup>), which is shared by human, baboon, and Rhesus cells.<sup>56,68</sup> Alleged differences between anti-LW and anti-Rh sera have been summarized by Mollison<sup>56</sup> and by Race and Sanger.<sup>68</sup> Wiener has denounced all these claims in the strongest terms.<sup>140</sup> He maintains that Landsteiner and Wiener's heterologous anti-Rh sera prepared in rabbits and guinea pigs simply detect another blood factor on the Rh agglutinin, thereby demonstrating again the multiple serologic specificities of a single agglutinin molecule.<sup>141</sup>

## MN, Ss, U System

The M and N antigens were discovered by Landsteiner and Levine in 1927.<sup>193</sup> Rabbits

were immunized with human red cells and, in addition to species specific antibodies, these animals developed antibodies that agglutinated some human cells (M) but not others (N). When the inagglutinable cells were used to immunize rabbits, antisera that specifically agglutinated these (N) cells resulted. Appropriately absorbed antisera are capable of identifying three red cell phenotypes: M, N, and MN, corresponding to the MM, NN, and MN genotypes respectively (Table 11-6). Human M and N antigens are thus distinguished by specific antibodies evoked in rabbits. They are poorly immunogenic in man; naturally occurring anti-M is rare and anti-N even rarer.<sup>56</sup> Occasionally anti-M is found as an immune antibody, usually after multiple transfusions or deliberate sensitization with M-positive blood.<sup>56</sup> Under such circumstances anti-M (and anti-N) antibodies are usually IgM in nature and have a thermal amplitude of 4 to 20° C, seldom extending to 37° C. They may therefore be detected as cold agglutinins. IgG anti-M antibodies have, however, been described.<sup>56</sup>

Very rarely hemolytic disease of the newborn due to anti-M may be noted, but since the infant would of necessity have to be type MN, the disease is either very mild or does not occur at all, as MN cells react more weakly with anti-M than do M cells.<sup>56</sup> In addition the antibody would have to be IgG in nature.

It has been suggested that the synthesis of M-N antigens is, in a way, similar to that of the A-B-H system, being the result of sequential gene-controlled changes in a common precursor substance.<sup>193,207</sup> Studies sup-

porting this view<sup>193,207</sup> were carried out with specific anti-M and anti-N sera of animal and human origin and with extracts from *Vicia graminea*, a leguminous plant, which interact with N-specific structures. It appears that both M- and N-activities are associated with the same macromolecule and that N-activity is found in M-preparations derived from cells with the genotype MM. Furthermore, mild acid hydrolysis of M-substance leads to a loss of M-specificity and uncovering of N-specificity. The decrease in M-activity and increase in N-activity are accompanied by a loss of N-acetyl neuraminic acid (NANA), suggesting that terminal NANA groups play a role in M-specificity. Treatment with neuraminidase, which removes all NANA from the red cell surface destroys not only M- but also N-activity. However, in contrast to the N-activity of M-antigen, N-antigen possesses no M-activity. Treatment of N-specific structures with  $\beta$ -galactosidase destroys all N-activity with the release of galactose, and some human anti-N sera are inhibited by galactose and other sugars possessing  $\beta$ -D-galactopyranosyl groupings, suggesting that  $\beta$ -D-galactopyranosyl structures, in addition to NANA, contribute significantly to N-specificity. This is further supported by the inhibitory effect of asialoganglioside and ganglioside I on anti-N sera.<sup>207</sup> Since treatment with neuraminidase destroys all M- and N-activity, NANA must also play a role in N-specificity.

The *Vicia* reagent, which is known to interact with N-specific structures, reacts even more strongly with partially hydrolyzed N- (and M-) antigens. The specificity of *Vicia* reagents is not dependent on NANA, but on terminal  $\beta$ -D-galactopyranosyl residues.

Thus, the following pathway for the biosynthesis of M- and N-specificities has been proposed<sup>207</sup>: The product of the N-blood group gene is the immediate precursor of the product of the M-blood group gene, while the allele to the M-gene is an amorph. The structure reacting with the *Vicia* reagent seems to lie in the biosynthetic pathway of the MN-macromolecule and appears before the N- or A1-determinants. The myxovirus receptor properties of these structures<sup>193</sup> ap-

pear concurrently with the N-group specificity.<sup>207</sup>

In 1947 an antiserum, designated anti-S, was discovered and was shown to react with about 55% of human red cells.<sup>193</sup> An anti-s serum that reacts with about 90% of human red cells was found later. The antigens defined by these sera appear to be the products of allelic genes, and although the Ss antigens cut across the MN distribution, a close association with the MN system can be demonstrated, with a bias towards MS/MS and Ns/Ns.<sup>68</sup>

U, an almost universal antigen present in all Caucasians and most Negroes, was discovered in 1953 as the result of a fatal transfusion reaction in a Negro woman.<sup>220</sup> The serum was designated anti-U. Anti-U is not simply anti-Ss, as was formerly believed, since anti-U sera will react with some cells of the type M<sub>s</sub>S-negative, s-negative, U-positive.<sup>26</sup> The allele u is at least relatively common in Negroes (1%) but is not found in Caucasians. Individuals lacking the U antigen are designated S<sup>u</sup>S<sup>u</sup>. Uu is closely associated with the Ss system since no S or s antigens have so far been detected in u individuals. It has been suggested that U might be a precursor substance for Ss antigens.

Anti-S may be present in patients who have received many transfusions and has resulted in fatal transfusion reactions. Occasionally it is found as a naturally occurring antibody. It may also cause hemolytic disease of the newborn. Some anti-S sera react only with SS red cells.<sup>193</sup>

Anti-s is very rare, but may cause hemolytic disease of the newborn. Anti-U, also rare, may arise following transfusion or pregnancy and has been associated with hemolytic disease of the newborn as well.<sup>56</sup>

**MN VARIANTS.** A large number of MNSs variants have been described. M<sub>1</sub> differs qualitatively from M, and appears to be related to M as A<sub>1</sub> is related to A. It is common in American Negroes (25% of M bloods), but only 5% of Caucasian M bloods are M<sub>1</sub>. The antigen tends to have a weaker intrinsic N content. Anti-M<sub>1</sub> sera are found in N indi-

viduals only and some have dual specificity (anti-M + anti-M<sub>1</sub>).

M<sup>k</sup> is a rare variant that lacks all MNSs, U, and other factors and is therefore analogous to the Rh<sub>null</sub> agglutinin.<sup>181</sup> Very weak antisera can be produced in rabbits and are occasionally found in man. M<sup>k</sup> individuals also suffer from a red cell membrane defect that causes red cells to agglutinate in "incomplete" antisera<sup>210</sup> (Chapter 27).

M<sup>s141</sup> is extremely rare outside Switzerland, where the distribution is 0.153%. The antigen gives no reaction with anti-M or N sera. Anti-M<sup>s</sup> is one of the commonest antibodies of the MNSs system, occurring in 1 to 4% of tested individuals. Because the antigen is so rare, however, it has not caused serious problems in blood matching.

A number of other rare variants have been described including He,<sup>191</sup> Hu,<sup>191</sup> M<sub>2</sub>,<sup>191</sup> M<sup>6</sup>, M<sup>7</sup> and M<sup>8</sup>,<sup>183</sup> M<sup>10</sup>,<sup>176</sup> N<sub>2</sub>,<sup>175</sup> N<sub>3</sub>,<sup>191</sup> R<sup>1</sup>,<sup>155</sup> S<sup>1</sup>,<sup>180</sup> V<sup>1</sup>,<sup>170</sup> and Vw (Gr).<sup>183</sup>

### The P System

In 1927, Landsteiner and Levine described yet another system by injecting human red cells into rabbits.<sup>56</sup> Human red cells reacting with these antisera were called P+, and those not reacting, P-.

The P blood group system is now thought to be determined by three alleles, P<sup>1</sup>, P<sup>2</sup>, and the very rare gene p, which in double dose results in the absence of P<sub>1</sub> and P<sub>2</sub> antigens<sup>150</sup> (Table 11-7). The recognition of increasing complexity within this system was largely due to the discovery of a rare antiserum,

**Table 11-7. Approximate Frequency of P-Phenotypes and Their Antibodies<sup>56,58</sup>**

Phenotype of Cells	Frequency of Phenotype	Antibody in Serum	Frequency of Antibody
P <sub>1</sub>	75%	—	—
P <sub>2</sub>	25%	Anti P <sub>1</sub>	90%*
P <sup>k</sup>	Very rare	Anti-P + P <sub>1</sub>	?
p	Very rare	Anti-P + P <sub>1</sub> + P <sup>k</sup> (Anti Tj <sup>a</sup> )	100%

\*At 0°C

Table 11-8. Reactions of Red Cells with Antibodies of the P System\*

Phenotype of Cells	Antibodies		
	Anti- $P_1$	Anti-P	Anti-P + $P_1$ + $P^k$
$P_1$	+	+	+
$P_2$	-	+	+
$P^k$	- or +	-	+
p	-	-	-

\*Also, see Wiener's interpretation of this system.<sup>217</sup>

anti-Tj<sup>a</sup>, which was soon shown to react with red cells of  $P_1$  and  $P_2$  phenotypes and was later also shown to contain anti- $P^k$  antibodies.<sup>177</sup> Wiener considers the evidence for a separate  $P^k$  antigen weak and has proposed a system of only two isoantibodies, anti-P and anti- $p'$ .<sup>217</sup>

The potential clinical importance of the P blood group system derives from the fact that antibodies may occur in the serum of individuals who lack the corresponding antigen (Tables 11-7 and 11-8). Thus, the anti- $P_1$  sera are found in  $P_2$  donors and react specifically with  $P_1$  cells. Anti-P sera react with  $P_1$  or  $P_2$  cells, but when these sera are absorbed with  $P_2$  cells, only anti- $P_1$  activity remains. Anti-P antibodies are found in pp and  $P^k$  subjects. Anti-Tj<sup>a</sup> reacts with  $P_1$ ,  $P_2$ , and  $P^k$  determinants and is found in individuals of the pp genotype.

Clinically significant transfusion reactions due to anti- $P_1$  must be exceedingly rare, although rapid destruction of isotopically labeled cells has been demonstrated.<sup>56</sup> Anti-P +  $P_1$ , found in pp and  $P^k$  individuals and as the Donath Landsteiner antibody in paroxysmal cold hemoglobinuria (Chapter 27), is very rare; it occurs predominantly in offspring from consanguineous marriages and in isolated geographic areas.<sup>68</sup>

$P_1$  antigen activity is thought to be associated with a glycosphingolipid structure<sup>192</sup> and D-galactose in  $\alpha$ -linkage appears to be the immunodominant sugar.

### Other Systems

**THE KELL SYSTEM.** The most important antigen in this system is K. Anti-Kell anti-

bodies were first found in the serum of a mother (Mrs. Kell) whose child probably had erythroblastosis fetalis,<sup>63</sup> and independently in a patient with a hemolytic transfusion reaction.<sup>218</sup> By means of an antibody recovered from the mother (Mrs. Cellano) of another child suffering from erythroblastosis fetalis,<sup>179</sup> a second antigen that was very common (99.8%) was found; this appeared to be allelic with K. It was therefore designated k. In England, 0.2% of the population have the genotype KK, 8.7% are Kk, and 91.1% are kk.<sup>56</sup> The first two genotypes are phenotypically identified as K-positive, the latter K-negative.

Other antigens of the Kell system include the antigens Kp<sup>a</sup> and Kp<sup>b</sup>,<sup>145,151</sup> and Sutter<sup>163</sup> which is defined by the antigens Js<sup>a</sup> and Js<sup>b</sup>.<sup>186,209</sup> Js<sup>b</sup> and Kp<sup>b</sup>, like k, have a very high frequency, but about 20% of Negroes are Js<sup>a</sup> positive. Kw is also part of the Kell system.<sup>56</sup> It is found in 6% of Caucasians and in 24% of Negroes. In the extremely rare phenotype K<sub>0</sub>, none of the above antigens is present.<sup>151</sup>

Naturally occurring anti-K antibodies are exceedingly rare,<sup>56</sup> but Kell-negative individuals may become sensitized following Kell-positive transfusions. Fortunately the Kell antigen is not as immunogenic as the Rh<sub>0</sub> antigen.<sup>221</sup> Production of anti-K antibodies by pregnant women is a relatively rare event, and most of those who have done so have had a history of previous transfusion, sometimes with blood from their husbands!<sup>56</sup> Once formed, anti-K is a potent cause of hemolytic disease of the newborn and may lead to severe transfusion reactions, even with acute renal failure.<sup>56,166</sup>

Anti-K antibodies may be either IgG or IgM, although they usually fail to agglutinate red cells suspended in saline solution. The antibody is best detected by the indirect Coombs' test.<sup>163</sup> In this system, IgG antibodies are most readily demonstrated by specific anti-IgG sera, whereas the presence of IgM antibodies is best detected by anti-complement sera.<sup>56</sup>

**THE KIDD SYSTEM.** This system, defined

by the two antigens  $Jk^a$  and  $Jk^b$ , was discovered in the study of a mother whose child had hemolytic disease of the newborn.<sup>63</sup> Like Kell, it behaves genetically as a two-allele system, but it also has a silent allele of infrequent occurrence that gives rise to the phenotype  $Jk(a-b-)$ . Approximately half the population has the phenotype  $Jk(a+b+)$ , a quarter are  $Jk(a-b+)$ , and a quarter are  $Jk(a+b-)$ .<sup>194</sup>  $Jk^a$  and  $Jk^b$  are rather weak antigens, but several instances of isoimmunization have been recorded, usually following transfusions.<sup>56,63,198</sup> Anti- $Jk^a$  is the more common antibody. In its presence, severe transfusion reactions may occur.

Anti- $Jk^a$  antibodies bind complement and are best demonstrated by the indirect antiglobulin test, especially if fresh complement is added.<sup>56</sup> The antibodies are usually IgG, but may be IgM.<sup>193</sup>

**THE LUTHERAN SYSTEM.** This is defined by an allelic pair of genes,  $Lu^a$  and  $Lu^b$ . The common phenotypes and their approximate frequencies are  $Lu(a-b+)$ , 92.35%;  $Lu(a+b+)$ , 7.5%; and  $Lu(a+b-)$  0.15%.<sup>63</sup> The frequency of the  $Lu^a$  gene appears to increase as one goes northward in Europe and varies between 2.1 and 9.1%, being highest in Danes and Norwegians.<sup>171</sup> It is found in Negroes, but is very rare in members of other races.<sup>68</sup> A rare silent phenotype,  $Lu(a-b-)$ , also has been encountered.<sup>158</sup>

$Lu^b$  appears to be more antigenic than  $Lu^a$ . Anti- $Lu^b$  has caused mild hemolytic transfusion reactions.<sup>156</sup> It may also have been responsible for a case of hemolytic disease of the newborn.<sup>56</sup> The anti- $Lu^a$  antibody is rare and has not been implicated in hemolytic disease. Most examples of anti- $Lu^a$  appear to represent "naturally occurring" antibodies. The antibody behaves as a complete agglutinin and is presumably IgM.<sup>56</sup>

**THE DUFFY SYSTEM.**<sup>157</sup> This consists of the alleles  $Fy^a$ ,  $Fy^b$ ,  $Fy$ , and possibly  $Fy^x$ .<sup>152</sup> The various genotypes and phenotypes, as well as their relative frequencies, are listed in Table 11-9. Of all the known blood group genes,  $Fy$  is thought to provide the greatest distinc-

Table 11-9. Duffy Genotypes and Phenotypes (in England)<sup>56</sup>

Genotype	Phenotype	Reaction with		Frequency (%)
		Anti- $Fy^a$	Anti- $Fy^b$	
$Fy^a Fy^a$	$Fy(a+b-)$	+	-	17
$Fy^a Fy^b$	$Fy(a+b+)$	+	+	49
$Fy^b Fy^b$	$Fy(a-b+)$	-	+	34
$Fy Fy$	$Fy(a-b-)$	-	-	0.3

tion between Negroes and Caucasians, its frequency being 83% in New York blacks, 90% in West Africans, and 3% in Europeans.<sup>69</sup>

$Fy^a$  appears to be a much "stronger" antigen than  $Fy^b$ ; sensitization is usually due to prior transfusion and has resulted in severe transfusion reactions as well as hemolytic disease of the newborn.<sup>56,68,167</sup> Anti-Duffy antibodies are best detected by the indirect Coombs' test. The antibody is usually IgG and frequently binds complement.<sup>56</sup>

Enzyme treatment of red cells, especially when impure preparations are used, may destroy the Duffy antigens, and enzyme matching and antibody techniques may therefore not detect anti-Duffy antigens or antibodies.<sup>56</sup> This apparently is not true when crystalline trypsin is used.<sup>56</sup>

**CHIDO.** The Chido antigen has a frequency of about 98%<sup>56</sup> and it is found in the plasma<sup>182</sup> as well as on red cells and, possibly, on the surface of leukocytes.<sup>215</sup> In cord blood, Chido antigen is found in the plasma but is very weakly expressed in red cells.<sup>182</sup>

The Chido antibody may cause difficulty in cross-matching in previously transfused patients.<sup>56</sup> The antibody gives a range of reactions and it is sometimes difficult to distinguish Chido-negative donors from those Chido-positive donors whose red cells react weakly or not at all.<sup>182</sup> This difficulty may be resolved by using an inhibition test based on the presence of Chido substance in the plasma of Chido-positive individuals.<sup>182</sup>

**DIEGO.** The antigen  $Di^a$  (Diego) defines another locus controlling antigen of the red

cells and saliva.<sup>178</sup> This antigen is not found, except as an extreme rarity, in the blood of Europeans and West Africans, but it is found in the blood of South American Indians, Japanese, and Chinese, and is generally presumed to be a Mongolian character. Its near absence in Eskimos is puzzling. Like other blood group antigens, it is inherited as a dominant character.

AUBERGER. This is a blood group that is found in 82% of Caucasians and probably in the same proportion of Negroes.<sup>200</sup> This antigen may be associated with the Lutheran system, since some Lu(a-b-) subjects are also Auberger-negative.<sup>56</sup>

"PRIVATE" AND "PUBLIC" ANTIGENS. In addition to the blood group systems described above, a number of very infrequent ("private") antigens and some common ("public") ones have been identified.

"Private" antigens<sup>55, 68</sup> include Levay, Wra, Be<sup>a</sup>, By, Rm, and others. They were discovered when they stimulated the production of an antibody by transfusion or when they caused hemolytic disease of the newborn. These rare antigens sometimes prove to be heralds of a new blood group system, as in the case of Wright (Wra), but sometimes they are rare members of established systems.

"Public" antigens are those that are possessed by the vast majority of people. These include Vel, Yr<sup>a</sup>,<sup>160, 173</sup> Sm,<sup>203</sup> Cs<sup>a</sup>,<sup>164</sup> and others.<sup>68</sup> Vel is of interest because it must be kept in mind when patients are not readily cross-matched.<sup>212</sup> Vel sensitization is known to produce mild to severe transfusion reactions, but hemolytic disease of the newborn has not been reported.

NEW GROUPS. New blood groups continue to be reported: Bu<sup>a</sup>,<sup>146</sup> Do<sup>a214</sup> and Do<sup>b</sup>,<sup>185</sup> Kamhuber,<sup>206</sup> etc. It would be rash to consider that the end of the list is in sight. The most interesting of the more recent crop is Xg<sup>197, 202</sup> for this is carried on the X chromosome; all other known blood group genes are carried on autosomes. This is proving to be a valuable tool in the study of human genetics.

## Blood Groups and Human Genetics<sup>196</sup>

Reference has been made in the preceding pages to the inheritance of the blood groups. Provided potent antisera are used and meticulous technique is employed, their value for studies of human genetics is apparent. As sharply distinguishable "fixed" characteristics of an individual, they serve as important markers of chromosomes and are useful in the study of linkage, the phenomenon whereby characters representing genes carried on the same chromosome travel together in inheritance. The only autosomal linkage groups so far disclosed in man all involve blood groups (Lu and Sc, Rh and elliptical cells, etc).<sup>68</sup> Many studies of autosomal linkage are in progress.<sup>201</sup> The X-linked blood group system, Xg, mentioned above, was found in one family in association with the gene for hemophilia B and that for color blindness.<sup>165</sup> Such a finding permits investigation of the linear order in which these three loci are arranged on the sex chromosome.

The blood groups also permit recognition of mosaicism<sup>189</sup> and of blood chimeras. These have been observed by study of the blood of nonidentical twins. In certain instances it was shown that only some of the red cell precursors were directly inherited, the rest having been acquired as in utero grafts of migrant embryonic cells from the opposite twin. Grafting of leukocytes took place as well.<sup>68, 153</sup> Chimerism has also been demonstrated following successful bone marrow transplantation.<sup>162</sup>

## Medicolegal Applications

Race and Sanger made the conservative estimate that more than a million different kinds of blood can now be distinguished.<sup>68</sup> Because of this individuality, blood groups can be applied to various problems of identity, parentage, and paternity. In addition the ABO and Lewis antigens of secretors (page 452) can be used in the examination of dried stains of saliva, seminal stains, plasma, and muscle extracts.

The reliability of blood typing for the exclusion of the possibility of parentage has been convincingly demonstrated and such tests have been accepted as decisive in many courts.<sup>68,213</sup> The routine use of the ABO, MN, and Rh-Hr systems for such purposes has been approved<sup>159</sup> and in the hands of qualified experts the use of other blood grouping systems is also feasible. Even when only the three above-mentioned blood groups of the mother, child, and alleged father are known, it is possible to exonerate 51% of all men wrongfully accused of paternity.<sup>211</sup> Blood groups can also be used to sort out babies accidentally interchanged in maternity wards and to decide whether twins are monovular or biovular.

In applying these procedures, however, thorough familiarity with the methodology involved is essential, as the consequence of errors obviously may be harmful for all concerned.<sup>305, 222</sup>

#### Application to Anthropology— The Ethnologic Distribution of Blood Groups

The blood groups are especially fitted to throw light on the moderately remote as well as the recent origins of man. Mourant<sup>187</sup> and Boyd,<sup>147</sup> in particular, have directed their attention to this topic. The utility of the blood groups has been limited largely by the sporadic character of many investigations and, in particular, by the scarcity of studies that encompass a whole country similar to those made in Sweden.<sup>188</sup> The value of the blood group characters is especially great in the study of isolated population groups, as in Africa. A number of blood group characters are largely confined to Africans, namely, R<sup>o</sup> (Dce) and V of the Rh system; H<sub>e</sub>, H<sub>u</sub>, and S<sup>u</sup> of the MNSs system; the silent Fy of the Duffy system; and Js<sup>a</sup> (Sutter)<sup>188</sup> As previously mentioned, the Diego antigen is found almost exclusively in Mongoloid peoples. Natural selection or genetic drift is thought to be the chief mechanism responsible for such differences.

There is a marked difference in blood

group frequencies between the peoples of eastern Asia and the aboriginal peoples of America. Polynesians most closely resemble American Indians and Eskimos, although this does not prove that the ancestral Polynesians came from America.<sup>188</sup> They differ from the American Indians and Eskimos in that there is a high frequency of M in the latter peoples, a characteristic shared with the Lamuts of north central Asia.

Defining race as a population that differs significantly from other human populations in regard to the frequency of one or more of the genes it possesses, Boyd divided the races of man into five main categories: European, African, Asian, American, and Pacific.<sup>148</sup> The European group was further subdivided into five groups: (1) Early Europeans, possessing, in particular, the highest incidence of the Rh-negative gene and no B; (2) Lapps, with the highest incidence of N in Europe, high Fy<sup>a</sup>, very low B, very high A<sub>2</sub>, and infrequent Rh-negative gene; (3) Northwest Europeans; (4) Eastern and Central Europeans; and (5) Mediterraneans, variations ranging from the findings characteristic of the Lapps to the strikingly high frequency of the Rh-negative gene in the Basques. Among the Vedda, the aboriginal inhabitants of Ceylon, there is a high frequency of B and very low frequency of the A genes.<sup>216</sup> Interesting differences in abnormal hemoglobins have also been found (Chapter 24). Group B is high in Chinese and in Asiatic Indians; A is high among the Eskimos.<sup>194</sup> The highest incidence of the rare genes R<sup>a</sup> and N<sup>2</sup> is in Chinese; A<sup>2</sup>, r, K, and R<sup>1w</sup> are virtually absent.<sup>222</sup> Among the white populations of the United States, group A is almost as common as O.<sup>172</sup> In Negroes, A is less frequent than O<sup>219</sup>; R<sup>o</sup> is very high.<sup>222</sup> The frequency of R<sup>a</sup> (CDE) is higher among American Indians than among any other peoples of the world; the r gene is completely absent. Reference has been made already to the high incidence of M among American Indians and of the Diego factor, which is nearly or completely absent in Europeans. In addition, Indians from the United States and Canada are predominantly group A and O,

and almost completely lack B. Among the Pacific peoples, Polynesians differ from Indonesians and Melanesians in that they have a higher incidence of M. The Australian aborigines are characterized by high frequencies of A<sub>1</sub> and a total absence of B, Rh-negative gene, and Lu<sup>a</sup>.

With the intense interest in this topic and the availability of other genetic markers, knowledge and understanding should grow. Computers have been invented none too soon.

## Methods of Blood Typing

In the attractive style in which their monograph<sup>68</sup> is written, Race and Sanger point out, "Blood group tests need some delicacy of hand and a great deal of concentration of mind. The importance of placing the right serum and the right cells in the right tube and of correctly recording the results is almost too obvious to mention. Yet to achieve accuracy a long apprenticeship in error seems necessary. A friendly but silent atmosphere is essential. Given silence, there is still danger of the mind wandering; this it must not be allowed to do, however routine the tests may be, however primrose the alternative paths." One wonders how often failure to attend to this admonition has resulted in the untimely death of the recipient of a blood transfusion.

Blood typing and matching require red corpuscles, serum or plasma, and antisera of high activity. The simplest procedure is to obtain a suspension of red corpuscles by placing one drop of blood from the finger into 3 ml of physiologic solution of sodium chloride or by making such a dilution in a white cell counting pipet; or, better still, venous blood is obtained, 0.5 ml of this blood is expelled into a test tube containing about 10 ml of physiologic sodium chloride solution, the tube is gently shaken to wash the cells, the supernatant fluid is poured off after centrifugation, and a fresh saline solution is added to make a 2 or 3% suspension.

Red cell concentrations greater than 2 or 3% should be avoided; otherwise the cells may absorb all the agglutinins present in

weak or diluted sera and fail to agglutinate with such sera. If agglutination does occur, it may be weaker or may develop more slowly than usual. Until the test is carried out, however, the red cells should be kept in concentrated form since they retain their sensitivity better in this way.

Typing sera are usually obtained from donors deliberately immunized against blood group factors. Testing sera should be inactivated before use; when they are fresh, complement is present and hemolysis may occur. Then the red corpuscles may disappear before agglutination can be observed. It is also noteworthy that testing sera deteriorate; therefore it is necessary to test the contents of each new vial against known cell suspensions.

There are two major classes of typing sera: those capable of agglutinating red cells suspended in saline solution (saline or *complete* agglutinins) and those incapable of doing so (*incomplete* agglutinins). Complete (saline) agglutinins were at one time considered to be "bivalent" and incomplete antisera were considered to be "univalent." It is now known that "incomplete" antibodies are also structurally bivalent, but are probably incapable of bridging the gap created between cells by repulsive electrostatic forces (Chapter 27).

Red cell antigens readily detected in saline solution at room temperature include those belonging to the ABH, Lewis, MN, P, and Lutheran systems (Table 11-10). A simple method for the detection of A and B antigens, for instance, is as follows:

One drop of anti-B serum is placed on the left side of a glass slide and one drop of anti-A serum on the right side. One drop of unknown cell suspension is mixed with each of these sera and the slide is then tilted back and forth for three to five minutes. The drops may then be covered with coverslips to facilitate examination under the microscope. Clumping that is visible with the naked eye occurs in accordance with the kinds of antigens found in the red cells.

A more satisfactory procedure is carried out in small test tubes (inside diameter, 7

**Table 11-10. Optimal Conditions for Erythrocyte Antigen-Antibody Reactions**

<i>Blood Group System</i>	<i>First Choice</i>	<i>Second Choice</i>
ABO	20° C saline	14°-16° C saline
Lewis	Antiglobulin ficin-antiglobulin enzyme-antiglobulin	14°-16° C saline
Ii	4°-16° C saline	4°-16° C enzyme
Rh Hr	Antiglobulin	Proteolytic enzymes, enzyme-antiglobulin
Mn	20° C saline	14°-16° C saline
Ss	Antiglobulin	Albumin-layer
P	14°-16° C saline	20° C saline
Kell	Antiglobulin	Albumin layer
Lutheran	20° C saline	Antiglobulin
Kidd	Antiglobulin	Enzyme-antiglobulin
Duffy	Antiglobulin	Albumin layer

From Moore et al.<sup>241</sup> courtesy of the authors and the Hunter Rose Company

mm). One drop each of unknown cell suspension, saline solution, and testing serum is mixed in such a tube. Blood suspensions of known groups should be prepared at the same time to serve as controls. The tubes are centrifuged at about 2000 rpm for about one minute. They are then replaced in a rack, which is gently shaken. When agglutination has not occurred, the sediment of packed red cells at the bottom of the tube can be shaken up into an even suspension. Positive reactions are indicated by the persistence of clumps of red cells the size of which depends on the intensity of the reaction. It is desirable to examine the contents of each tube microscopically. If clumping occurs only with the anti-B serum, the red corpuscles must contain B agglutinin; if clumping occurs only with the anti-A serum, the red corpuscles must have A agglutinin; if clumping occurs with both sera, the red corpuscles must have A and B agglutinogens; and if no clumping whatever occurs, the red cells must be group O.

Since "incomplete" antibodies cannot be detected readily with saline techniques, special procedures have been developed for their demonstration. The tests are of two basic types:

#### 1. ANTIGLOBULIN OR COOMBS' TEST (see

Fig. 27-1). The direct antiglobulin test<sup>231</sup> utilizes a heterologous IgM antihuman gammaglobulin serum to agglutinate cells already coated with "incomplete" (IgG) antibodies in vivo. For purposes of red cell typing, however, the "indirect" antiglobulin test is more useful. In this modification, red cells are first incubated with a battery of specific antisera (if red cell typing is to be done) or a battery of known red cell types is incubated with an unknown serum (if the specificity of an antiserum is to be determined). After cells and antisera have had a chance to combine, the red cells are washed and are then reacted with heterologous antiglobulin sera as in the direct antiglobulin test. Agglutination indicates the presence of antibodies on the red cells.

The indirect antiglobulin test is frequently carried out with red cells that have been treated with proteolytic enzymes<sup>229</sup> such as papain, ficin, and bromelain. This process modifies the red cell envelope in such a way as to permit greater binding or more avid binding of incomplete antibodies. The use of such agents has greatly increased the sensitivity of tests for incomplete antibodies.<sup>233</sup>

In addition to its usefulness in the study of Rh antibodies, the antiglobulin test serves to demonstrate the Kell, Kidd, and Duffy systems of blood groups (Table 11-10) and

is important in the study of hemolytic anemias (Chapter 27). A great variety of techniques have been described for demonstrating agglutination.<sup>68</sup> Deserving special mention is the slanted capillary tube method which some workers have found very satisfactory for routine Rh testing.<sup>232,244</sup>

**2. PROCEDURES DIMINISHING REPULSIVE ELECTROSTATIC FORCES BETWEEN CELLS.** The reaction of incomplete antibodies with red cells may also be detected by a variety of procedures that diminish the repulsive electrostatic forces between cells and allow their approximation to such an extent that incomplete (IgG) antibodies are capable of bridging the gap between them.<sup>26,244</sup> These techniques include (a) the addition of albumin and other colloids that are presumably capable of diminishing the dielectric constant of the medium (Chapter 27); (b) the enzymatic treatment of red cells that apparently reduces the repulsive force between red cells by removal of charged surface structures, principally sialic acid residues; and (c) the reduction of the ionic strength of the medium by substituting isotonic sucrose for saline. The last method is particularly useful in automated systems.<sup>248</sup>

### Tests of Compatibility

In selecting compatible blood a minimum of three major procedures must be carried out: first, the recipient's ABO and Rh groups must be determined, as already outlined; then a compatible donor blood must be selected; and, finally, donor red cells must be cross-matched against the recipient's serum

### Cross-Match Procedure

The cross-match procedure is essential for several reasons:<sup>56</sup> (1) either donor or recipient may have been wrongly grouped; sometimes there may be subgroup differences, as when the donor is A<sub>1</sub>, but the recipient is A<sub>2</sub>, with anti-A<sub>1</sub> antibodies in his serum; (2) the recipient may carry other "natural" antibodies such as anti-P<sub>1</sub>, anti-Le<sup>a</sup>, anti-Le<sup>b</sup>, or anti-H; (3) to detect anti-Rh antibodies in Rh-

negative recipients or incompatibility due to anti-rh', anti-hr', etc; (4) to detect reactions due to other isoantibodies such as anti-K, anti-Fy<sup>a</sup>, and others.

The cross-match procedure consists of: (1) Reacting recipient serum against donor cells suspended in saline solution (page 469). (2) Testing recipient serum against donor cells in the indirect antiglobulin test (page 470). Since weak antibodies in the recipient's serum may not react with incompatible donor cells in their second or third week of storage, the recipient's serum must also be tested against a well-preserved sample representative of all clinically important antigens. (3) An enzyme test. This is included by some laboratories for the detection of Rh antibodies not reacting by the indirect antiglobulin test.<sup>244</sup>

### Sources of Error and Confusion

Confusion in typing and matching may occur as the result of pseudoagglutination or autoagglutination.

*Pseudoagglutination* refers to rouleau formation and clumping that occur when the sedimentation rate of the blood is accelerated. This is most likely to cause confusion when the slide method of typing is employed and usually disappears when pressure is exerted on the coverslip or when saline solution is added. Since the patient's serum, and particularly his plasma, contain the factors causing rapid sedimentation of red corpuscles, pseudoagglutination may cause difficulty when the patient's serum is cross-matched against the blood of prospective donors. Dilution of the serum with one or two volumes of saline solution abolishes pseudoagglutination.

*Autoagglutination* refers to the agglutination of the red cells of an individual by his own serum or plasma. Its most troublesome form is cold hemagglutination (Chapter 27). Although this phenomenon, like group-specific isoagglutination, may persist in spite of considerable dilution, it occurs usually at low temperatures, whereas specific isoagglutination is little affected by changes of temperature from 0° to 37° C. Consequently, if the test is performed at 37° C, particularly

with red cells washed with normal saline solution at this temperature, autoagglutination can be prevented.

If in blood grouping an "AB reaction" is obtained, a control test of the patient's cells in his own serum should be set up. If the reaction has been caused by autoagglutinins, agglutination will take place under these circumstances as well.

Autoagglutinins may cause confusion when the patient's serum is cross-matched against the blood of prospective donors. They can often be removed by absorbing the patient's serum with his own cells at 0° to 5°C.

Erythrocytes from old blood samples may sometimes be agglutinated by most sera irrespective of the blood groups found on those cells. This phenomenon of *panagglutination* may, therefore, be a cause of error in blood typing. It has been shown that this "Heubener-Thomsen-Friedenreich phenomenon" is due to the fact that filtrates of certain bacteria contain an enzyme that acts on human red cells, changing a latent antigen to an active one ("T-antigen"). A similar phenomenon has been described as occurring transiently *in vivo*.<sup>217</sup>

Irregular and atypical isoagglutinins occurring naturally, such as those reacting with subgroups of A and the agglutinogens P and M, generally give much weaker reactions than typical isoagglutinins and react only exceptionally at 37° C. They may therefore be confused with cold autohemagglutinins. Other irregular isoagglutinins resulting from isoimmunization, especially the Rh-Hr antibodies, generally react at body temperature and may be quite potent, giving rise to dangerous hemolytic transfusion reactions. Special procedures are required to detect some of these.

## Collection and Preservation of Blood

The technology of collection and preservation of blood for transfusion has been greatly improved. Plastic collecting bags with one-piece tubes and disposable needles have replaced glass containers, vacuum bottles, and

rubber tubing with their potential hazards. Various safeguards have been introduced in blood banking and transfusion practices.<sup>211,215</sup> Double and quadruple bags are available for the plasmapheresis of donor blood in a closed system, thereby eliminating the most common cause of bacterial contamination. In addition, the nonwettable surface of the plastic minimizes the danger of clot formation. Pilot tube samples can be made an integral part of the plastic tubing so that the danger of error from mix-up of tubes can be avoided. The blood preservative is prepared and autoclaved in the bag at the time of manufacture and quality control and pyrogen testing can be carried out efficiently and safely by the manufacturer.

### Red Cell Storage Lesions

When blood is stored in liquid medium, a series of readily discernible biochemical changes that influence the viability of stored cells occurs.

1. The first important change consists of a sharp drop in 2,3-diphosphoglyceric acid (2,3DPG) levels, which may reach 20% of normal within five days.<sup>226,230</sup> The level of 2,3DPG within the red cell is an important determinant of hemoglobin function:<sup>236</sup> falling 2,3DPG levels are accompanied by a shift to the left in the oxygen dissociation curve, indicating a higher oxygen affinity of hemoglobin (Chapter 3). This increased oxygen affinity of stored blood may be of critical clinical importance; a seriously ill patient receiving large doses of blood with a high affinity for oxygen may look pink, but his tissues may not benefit because the hemoglobin of 2,3DPG-depleted red cells does not unload oxygen as readily as the hemoglobin of normal cells. Transfused red cells totally depleted of 2,3DPG can regain half their normal level within 24 hours or less,<sup>230,242</sup> but this reconditioning may not be rapid enough for the seriously ill patient.

2. The concentration of ATP falls much more gradually than does the level of 2,3DPG, while the concentration of ADP and AMP first rises but then decreases as AMP

is irreversibly deaminated to IMP, IMP being subsequently catabolized to hypoxanthine.<sup>227</sup>

3. As the concentration of ATP falls, red cells lose the ability to phosphorylate glucose, and the sodium-potassium pump breaks down. Potassium leaks from the cell and sodium gains entry into the cell. As a result the osmotic fragility of stored red cells is increased and some undergo spontaneous lysis.

When stored blood is reinfused, the most damaged cells are removed within the first 24 hours, whereas the remainder appear to survive normally or almost normally.<sup>236,251</sup> When freshly collected ACD blood is transfused, an average of 5% of the cells is lost during the first 48 hours post-transfusion. Approximately 90% of the red corpuscles survive in usable form after 14 days' storage but only 70% remain after 24 days. A 70% long-term survival rate usually is considered satisfactory for transfusion purposes.

The loss of organic phosphates is one of the most important aspects of the storage lesion (see above); therefore attempts have been made to preserve the concentration of organic phosphates within the red cell. Thus the addition of adenine at the beginning of storage prevents the loss of ATP and enhances the *in vitro* preservation of red cells considerably.<sup>241,250</sup> The addition of adenine is not helpful once the red cells have lost a considerable portion of their ATP, since they have then lost their ability to phosphorylate glucose, incorporate adenine into adenine nucleotides, or phosphorylate AMP and ADP to ATP. However, if inosine is added to blood, even after several weeks of storage, a prompt boost in 2,3DPG and ATP levels occurs,<sup>230,250</sup> because the phosphorolysis of inosine yields ribose-1-phosphate which in turn can be metabolized to high-energy phosphates. There is a concomitant improvement in the storage viability of red cells. Unfortunately the potential toxic effects of intravenously administered inosine may limit its usefulness; effective amounts impose a high purine load on the kidneys and dangerous hyperuricemia may develop.

## Anticoagulants

Several types of anticoagulants are available for liquid storage of red cells. *Acid citrate dextrose* (ACD) solution (NIH Formula A) contains 7.3 g citric acid, 22.0 g sodium citrate, and 24.5 g glucose per liter of solution. Of ACD Formula A, 15 ml must be available for every 100 ml of blood collected. ACD Formula B is somewhat more hypotonic: 1 liter of solution contains 4.4 g citric acid, 13.2 g sodium citrate, and 14.7 g of glucose; 25 ml of ACD Formula B must be available per 100 ml of blood.

Better initial survival as well as a longer red cell "half-life" ( $t_{1/2}$ ) were observed when a citrate-phosphate dextrose (CPD) preservative was used.<sup>228,236</sup> CPD represents only a slight modification of the basic ACD formula and contains 3.2 g citric acid, 25.8 g sodium citrate, 25.0 g of glucose, and 2.18 g of  $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$  per liter of solution. Fourteen milliliters of CPD solution must be available per 100 ml of blood collected. The net loss of intracellular potassium and the net gain in plasma potassium were found to be significantly less in CPD than in ACD blood, and plasma potassium levels were lower throughout storage,<sup>237</sup> but the formulaic inorganic phosphate of CPD results in higher plasma phosphate levels than in ACD blood. When CPD is used as a preservative the blood-preservative mixture is somewhat more alkaline than when ACD is used and this results in better 2,3DPG preservation.<sup>230</sup>

*Heparin* has also been used as a preservative, but when the blood is cooled to 4° C there is a marked rise in the pH and consequently a rapid loss of red cell ATP. Heparinized blood must therefore be used within 48 hours of collection. Heparinized blood is particularly popular for the priming of extracorporeal circuits, but, for these purposes, glucose and low molecular-weight dextran may be even better.<sup>234</sup>

## Frozen Red Cells

In the preservation of blood for long periods, measured in years, glycerol has been

found to protect cells against internal crystal formation at temperatures of  $-80^{\circ}\text{C}$  and lower.<sup>255,256</sup> When needed the blood can be thawed, warmed, and reconstituted with only a 20% loss of red cells. The freezing of red cells in liquid nitrogen also holds promise as a method of preservation.<sup>252</sup>

Frozen red cells have unique applications because of their almost unlimited shelf life, the superior preservation of organic phosphates such as 2,3DPG and ATP, and the extent to which leukocytes, platelets, and plasma are removed in the various washing procedures required during deglycerolization.<sup>255,257</sup> The incidence of hepatitis appears to be markedly decreased.<sup>251</sup> The clinical usefulness and safety of frozen blood have been tested in various clinical situations, including its use in the emergency therapy of combat casualties.<sup>255</sup> A particularly useful role for frozen blood appears to be the establishment of a "rare blood" bank for the stockpiling of unusual blood types.<sup>259</sup>

## Blood Transfusion

The transfusion of blood from one dog to another was achieved successfully in the 17th century,<sup>270</sup> but the transfusion of blood from man to man, with rare exceptions,<sup>271</sup> was not accomplished until the mysteries of serologic incompatibility were disclosed, as discussed above. In the earlier attempts, blood was collected in paraffin-lined containers, or "direct" transfusions were given, in which communications were made between the vessels of the donor and those of the recipient. Sodium citrate was introduced as an anticoagulant for blood in 1914 and two decades later it was shown that cadaver blood, because of the fibrinolysis which takes place after death, could be used for transfusion without mixing it with anticoagulants.<sup>284</sup> It was not, however, until the concept of blood banks was introduced and the exigencies of World War II stimulated the investigation of methods for blood preservation<sup>278</sup> that blood became readily available and blood transfusion became popular. This, however, has not been an unmixed blessing, for familiarity has bred

thoughtlessness and now, in civilian practice at least, blood transfusion is carried out all too frequently when it is not required and without due consideration of the risks involved. It was found in one study that 27% of multiple and 60% of single unit transfusions were not indicated!<sup>261</sup>

### Indications

Blood transfusion must be regarded as a rather dangerous and potentially lethal form of therapy and clear indications for its use must therefore exist. The physician must consciously and deliberately weigh the potential benefits against the known risks. In chemotherapy the ratio of the two is known as the therapeutic index and similar concepts are well applied to the use of blood and blood products.

When transfusion seems indicated, the physician must also decide whether the patient needs whole blood or blood components and how much needs to be given.

**WHOLE BLOOD.** By far the most important use of whole blood is for the restoration of an adequate blood volume after hemorrhage or trauma. In such situations the restoration of an adequate volume is usually more important than an adequate red cell mass; therefore whole blood transfusion has no equal. Saline, plasma, and "plasma expanders," such as low molecular-weight dextran, may be useful stopgap measures until the typing and matching have been done. However, the use of dextran may give rise to difficulties in blood matching; therefore an adequate blood sample should be removed for matching before dextran has been given.

Accurate assessment of the amount of blood lost is difficult, although an estimate based on the blood pressure, pulse rate, and the patient's general appearance can often be made. The signs and symptoms of severe blood loss include pallor, vasoconstriction, sweating, thirst, air hunger, and restlessness. When such manifestations of oxygen want are present, transfusion is always mandatory. When there is evidence of acute ongoing

hemorrhage, however, it is unnecessary to wait for the development of these extreme signs and symptoms, as many adults may lose as much as 1500 ml of blood without showing such clinical signs, so long as they remain in the horizontal position.<sup>274</sup> Under such circumstances the blood pressure and other clinical parameters should be observed with the patient in the "tilted" as well as in the horizontal position. Acute blood loss in excess of 1500 ml produces clinical shock in most persons.

If the systolic blood pressure is less than 100 mm of mercury, the blood volume is probably less than 70% of normal, but it is dangerous to rely on this sign alone when the patient's pre-hemorrhage pressure is not known. Thus a systolic pressure of 120 mm of mercury may be very significant in a hypertensive patient whose usual systolic pressure is 200 mm of mercury. Similarly the pulse rate is by itself an unreliable guide, although in an actively bleeding patient a persistent pulse rate of 100 or more probably indicates blood loss in excess of 20%. Estimation of the hemoglobin level or hematocrit value may be misleading shortly after an acute hemorrhage, since compensatory vasoconstriction will keep these at normal levels until the intravascular volume has been re-expanded with fluids from extravascular sources. This usually occurs between three and six hours after hemorrhage, and a rapidly falling hemoglobin level during this period indicates blood loss of serious proportions. The skillful physician will, of course, not allow these signs of major blood loss to develop.

The loss of blood during surgical procedures is partly a reflection of the skill and care of the operator and, to a lesser extent, the type of operation. The common practice of replacing all blood losses by transfusion is totally unjustified. The loss of 500 ml of blood is well tolerated by most patients. Indeed, even patients undergoing open-heart and other major surgical procedures in which blood loss exceeds 1000 ml can be managed without blood transfusion, so long as intravascular volume is maintained with crystal-

loid solutions<sup>268</sup> or even with simple saline infusions.<sup>279</sup> When noncolloid solutions, such as buffered saline are used, the volume administered needs to be two to three times the volume of blood lost.<sup>275,279</sup>

Whole fresh blood is indispensable for exchange transfusions such as those used in the treatment of hemolytic disease of the newborn (Chapter 27). It is also most commonly used to prime the equipment for extracorporeal shunts, including renal hemodialysis units and heart-lung machines.<sup>261,282</sup> It has been suggested by some, however, that packed red cells suspended in suitable balanced salt solutions are preferable for these purposes,<sup>262</sup> while others have recommended priming extracorporeal circuits with blood substitutes such as crystalloid or colloid solutions.<sup>234,317</sup>

**PACKED RED CELLS.** Except as outlined in the previous section, most transfusions are given in order to improve the oxygen-carrying capacity of the blood. The only component of donor blood that can accomplish this is the red cell and thus, when improvement of the oxygen-carrying capacity is the objective, all other blood components are wasteful or dangerous. The plasma is needed for the preparation of various plasma fractions such as albumin, cryoprecipitate, or gamma globulin, and platelets are in high demand for patients suffering from thrombocytopenia. In addition, for improvement of the oxygen-carrying capacity the various unneeded components are potentially dangerous to the recipient; leukocytes and platelets carry transplantation antigens to which the patient may become sensitized. The resulting isoantibodies may later give rise to transfusion reactions (page 479), isoimmune leukopenia of the newborn (page 507), and rapid elimination of transfused platelets (Chapter 12). In patients undergoing hemodialysis, blood transfusion may prejudice the survival of an organ transplant in the future.

The transfusion of plasma, citrate, and electrolytes that are part of whole blood also expands the circulating blood volume and this may be poorly tolerated in patients with in-

Table 11-11. Packed Red Cell Products Prepared from Blood Collected in Plastic Containers

Product	Hematocrit (%)	Percentage of Original Unit			Method of Separation*	Permissible Storage Life at 1-6° C after Preparation
		Leukocytes	Platelets	Plasma		
Sedimented cells	65-70	100	100	30	Generally open	Not > 24 hr
Centrifuged cells†	80	100	100	15	Open	Not > 24 hr
					Closed	Up to 21 days from collection
Centrifuged cells† with buffy coat squeezed off	>90	30	<30	5-10	Open	Not > 24 hr
					Closed	Uncertain—possibly up to 10-15 days from collection
Washed cells (continuous-flow centrifuge)	As desired	<10	<10	<1	Open	Not > 3 hr
Thawed resuspended cells (continuous flow centrifuge)	As desired	0	0	<1	Open	Not > 3 hr

\* Plasma removed by breaking of container's hermetic seal (open) or into attached bag with hermetic seal unbroken (closed)

† Centrifugation permissible for blood stored for not > six days from date of collection

recipient circulatory failure (page 485). In addition, plasma proteins are themselves antigenic and there have been well-documented instances of anaphylactic transfusion reactions, involving primarily anti-IgA antibodies in recipients lacking this particular immunoglobulin (page 485). Plasma also carries isohemagglutinins; multiple units of O blood given to A, B, or AB individuals could lead to the destruction of the recipient's own red cells. The protein content of plasma is inconsequential in the treatment of patients with hypoproteinemia and malnutrition for whom it is frequently prescribed, its beneficial effect on wound healing is a myth.

The available packed red cell preparations and their properties are listed in Table 11-11.<sup>262</sup> It becomes immediately apparent that most techniques efficiently reduce the amount of plasma and anticoagulant, thereby

minimizing the possibility of circulatory overload, electrolyte disturbance, and the effects of transfused isohemagglutinins. Only one of these techniques, however, reduces the concentration of leukocytes and platelets sufficiently to prevent isosensitization. In only two of these preparations is the concentration of plasma proteins reduced to a small enough fraction of the original (<1%) to reduce the incidence of transfusion hepatitis (page 486).

*Sedimented cells* are most readily available, but the recovery of plasma is inefficient. All the leukocytes and platelets remain. Since withdrawal of plasma from sedimented cells usually breaks the hermetic seal of the original container, the unit must be administered within 24 hours to avoid the risks of bacterial contamination.

*Centrifuged cells* permit the salvage of more

plasma but offer no additional advantage in regard to leukocyte and platelet sensitization and the risk of hepatitis. The plasma, however, is usually removed within a closed system and centrifuged cells may therefore be stored at 4° C for up to 21 or 28 days.<sup>285</sup>

Centrifuged blood from which the buffy coat has been squeezed off has the highest hematocrit value of any of the products and saline or balanced salt solutions generally have to be added just prior to use to reduce viscosity and facilitate transfusion. It is obvious, however, that about 30% of the original leukocytes remain behind and while this may be sufficient to reduce the incidence of reactions in weakly sensitized patients, it is ineffective in patients with a moderate or high degree of isosensitization. A more satisfactory buffy-coat-poor preparation can be obtained by centrifuging the plastic container in the inverted position and draining off the red cells from below.<sup>262</sup> When about 25% of the red cell mass is left behind less than 10% of the original white cells will be found in the final product.

*Red cells washed in saline solution* by manual techniques offer little advantage over the centrifuged cells described above. Cells washed in a continuous flow centrifuge will, however, be remarkably free of plasma, leukocytes, and platelets. This also is an ideal way to prepare washed red cells for patients suffering from PNH (Chapter 29).

The characteristics of *frozen red cells* have been discussed previously (page 474).

**USES.** 1. Packed cell transfusions are indicated for patients with certain forms of *hemolytic anemia*, especially when they are in aplastic crises. Such patients are frequently very ill and may have hemoglobin values as low as 2 to 3 g/dl. Their cardiovascular system often is on the verge of collapse and even a small transfusion may precipitate cardiac failure and death. They can be managed safely only by constant central venous pressure monitoring and by exchanging packed cells cautiously for their blood. A careful balance sheet must be kept and initially it is well to remove perhaps 10% more volume

than is replaced. Packed cells should be as fresh as possible. An anemic patient with an elevated venous pressure at the start of therapy must *never* be transfused without continuous central venous pressure monitoring and the concomitant removal of blood as necessary, since, otherwise, cardiac failure will almost inevitably become worse.<sup>265,266</sup> Digoxin and diuretics may on occasion be useful ancillary measures, but are not as reliable as an exchange transfusion.

In acquired forms of hemolytic anemia, transfused red cells may be destroyed as rapidly as are the recipient's own cells. When hemolysis is due to an antibody it may be possible to identify its specificity; in such cases it may be possible to find compatible blood (Chapter 27).

In the more chronic forms of hemolytic anemia a state of equilibrium frequently has been reached and, in such patients, blood transfusions have little to offer.

2. Packed red cells are the treatment of choice for the support of patients with *chronic hypoplastic anemias* for whom no other forms of therapy are available. Such anemias include the various aplastic anemias (Chapter 56), the anemia accompanying chronic renal disease (Chapter 19), and others. Important considerations regarding the use of blood transfusion in patients with these anemias are discussed below.

3. Patients suffering from acute and chronic leukemia, lymphomas, or other malignant disease may need packed cell transfusions, especially while undergoing therapy.

4. Transfusions have been used to suppress *endogenous erythropoiesis* in patients with sickle cell anemia<sup>283</sup> or thalassemia,<sup>260</sup> but the danger of transfusion hemosiderosis limits the usefulness of this method (see Chapters 25 and 26).

5. Patients suffering from chronic anemias due to a deficiency of vitamin B<sub>12</sub> or iron usually respond well to specific therapy and do not require transfusions. Occasionally, however, a patient when first seen will be *critically ill* with cardiac failure, angina pectoris, cerebral insufficiency, or infection, sometimes complicated by leukopenia and

thrombocytopenia. Under such circumstances transfusion may be lifesaving<sup>27,2</sup> (Chapter 15). It should be given under close supervision with constant monitoring of central venous pressure, and, when necessary, by the exchange technique, as described elsewhere.

Some physicians follow the deplorable practice of transfusing patients whenever the hemoglobin value is below an arbitrarily set figure. Similarly, the insistence of some surgeons that the hemoglobin concentration be "normal" prior to a surgical operation is a form of superstition; the concept of "chronic shock" has no foundation in fact. Blood transfusion is not a tonic nor is it a placebo. In most patients with chronic anemia of moderate severity the anemia has developed so gradually that these patients have adapted to the new hemoglobin level. Such symptoms as may be present are often due to the underlying disease of which the anemia is merely a sign. As a rule in such a patient an equilibrium between red cell production and destruction has been reached and blood transfusions only serve to alter this balance temporarily. At the same time they subject the patient to unnecessary risks.

It is true, of course, that there is a certain level of hemoglobin below which the physiologic adjustments to anemia (Chapter 13) begin to fail and symptoms such as excessive weakness, orthopnea, and even angina will develop. These symptoms can be avoided by giving blood transfusions, but, as a rule, they do not appear in adults until the volume of packed red cells has dropped below 0.25 l/l and the hemoglobin level is under 8 g/dl. Children tolerate even lower levels. At very low levels, however, the mortality from anemia becomes considerable.<sup>26b</sup>

### Mode and Route of Administration

It is most important that the label of the bag or bottle of blood be checked against the patient's name and identification numbers. If any inconsistencies appear, the blood should not be given. Under most circumstances it is not necessary to warm the blood before transfusion unless large quantities have to be given quickly.<sup>58</sup>

Blood should be given slowly at first, since this will allow for detection of unexpected transfusion reactions before the patient is seriously harmed. After the first 30 minutes, blood usually is given at the rate of 200 to 400 ml/hour in adults; in many patients without cardiorespiratory problems, rates of 500 ml/hour are perfectly safe.<sup>56</sup> Packed cells should be infused at about two thirds the rate of whole blood. In patients with incipient cardiac failure or elevated venous pressure, blood must be given much more slowly and, preferably, by exchange transfusion (page 477).

In infants and children the blood is given at a rate of 2 to 6 ml/kg of body weight/hour, depending on the condition of the child, but under most circumstances no more than 15 to 20 ml/kg are given at any one time. When blood is lost acutely, for instance, by hemorrhage, larger amounts of blood may, and frequently must, be given quickly in order to save the life of the patient.

The amount of blood required to raise the hemoglobin to a desired level can be calculated easily if one remembers that a hemoglobin concentration of 15 g/dl corresponds to a red cell volume of about 30 ml/kg of body weight. Since most packed cell preparations have a hematocrit value of about 0.66 l/l, 3 ml of packed cells/kg of body weight will raise the hemoglobin concentration by 1 g/dl.<sup>56</sup> If whole citrated blood is used (hematocrit = 0.33 l/l), twice as much volume has to be given in order to achieve the same result.

The usual site for transfusion is one of the antecubital veins of the forearm, but the superficial veins of the legs and, in infants, the scalp veins also may be used. When, for various reasons (peripheral circulatory failure, extensive skin burns, etc), veins are not accessible for transfusions, blood and other suitable fluids may be given via the bone marrow,<sup>287</sup> but the procedure is not without danger. For extreme emergencies, as in the treatment of shock resulting from a rapid decrease in blood volume when conventional methods of therapy have failed, transfusions have been given intra-arterially,<sup>280</sup> but it is doubtful whether this is ever justified, except

into the arterial stump left by a destroyed arm or leg of a person in severe shock. Intraperitoneal transfusion is a simple procedure that can be accomplished quickly and easily,<sup>288</sup> but absorption of blood is slow.

### Complications of Blood Transfusion

Transfusion reactions are conveniently classified as *immune* or *nonimmune*. The former include (1) reactions due to red cell incompatibility and (2) reactions due to leukocyte and platelet incompatibilities, as well as other forms of allergic reactions. Non-immune transfusion reactions include (1) those caused by overloading of the circulation, (2) those related, in particular, to massive transfusions, (3) transmission of infections, and (4) miscellaneous ill-effects, such as thrombophlebitis, air and fat embolism, and transfusion siderosis.

### *Immunologically Mediated Transfusion Reactions*

#### 1. Hemolytic Transfusion Reactions

Two different mechanisms cause hemolysis of mismatched blood—hemolysis may be due to rapid intravascular breakdown of transfused cells or it may be due to extravascular destruction of antibody-sensitized erythrocytes, predominantly in the reticuloendothelial system. The immunologic basis of the two types of hemolysis and the kinetics of antibody-mediated red cell destruction are discussed in Chapter 27. This section will deal predominantly with the clinical manifestations of transfusion reactions.

#### *Intravascular Hemolysis of Red Cells*

This type of transfusion reaction is most commonly associated with incompatibility in the ABO system, since anti-A and anti-B antibodies are most commonly IgM and are capable of binding complement, leading to almost instantaneous lysis of transfused cells in a sensitized individual.

The most common cause of ABO incom-

patible transfusion reaction probably is human error. Other causes include the weak  $A_2$  and  $A_2B$  agglutinogens that may be missed during typing. This problem was discussed earlier (page 472); other atypical blood groups, such as  $A_x$  (Wiener's "C"), also may be associated with hemolytic transfusion reactions.<sup>365</sup>

Occasionally severe transfusion reactions have been caused by the use of "universal donor" blood (O Rh negative), usually under emergency conditions when not enough time was available to type and cross-match compatible blood. While this blood can often be employed successfully, especially if it has low titers of anti-A and anti-B, its routine administration in emergencies cannot be recommended. In most circumstances, transfusion can be delayed for 15 or 30 minutes while the patient's ABO and Rh types are ascertained so that appropriately grouped blood can be provided, even if there is not sufficient time for a cross-match. Sometimes severe hemolytic reactions have been observed even when the anti-A agglutinin titer of the donor's blood was not unusually high.<sup>369</sup> The dangerous anti-A antibodies in such instances have shown characteristics of an "immune" type of antibody in that they agglutinated more readily at 37° C than at lower temperatures, agglutinated red cells only in serum or albumin, fixed complement and acted as hemolysins, and were relatively resistant to the addition of soluble A and B substance. Such agglutinins have been encountered particularly in persons who have been immunized with horse serum or similar agents that might have stimulated the production of such antibodies,<sup>369</sup> as well as in group O mothers immunized by type A or B infants.

When group O is used as universal donor blood, the titer of isoagglutinins must first be determined. When necessary the presence of a safe level can be established quickly by diluting the serum of the donor 1:200 and then mixing it with a suspension of appropriate red cells. If agglutination does not occur under these conditions, the blood may be regarded as safe. Additional qualifications that should be required of "safe universal" group O blood are that it be (1) truly group

O and not  $A_2$  or  $A_2B$  mistaken for O or B; (2) Rh negative; and (3) lacking atypical iso-antibodies such as anti-H, anti-M, and anti-P. With the isolation of group-specific A and B substances, it is possible to reduce the titer of antibodies in group O blood by adding these substances to the blood.<sup>342</sup>

**CLINICAL MANIFESTATIONS.** The administration of incompatible blood usually is associated with the onset of symptoms before much blood has been introduced; if the transfusion is stopped, no serious harm may result. The symptoms observed include restlessness, anxiety, flushing of the face, precordial oppression and pain, an increase in pulse and respiratory rates, generalized tingling sensations, and pain in the back and thighs. Nausea and vomiting may follow and cyanosis, shock with cold, clammy skin, coma, and a failing pulse may develop. A chill, followed by a rise of temperature to 105° F or higher, and even delirium may ensue. Leukopenia is followed by leukocytosis.

Not infrequently a *hemorrhagic tendency* develops immediately after the transfusion of incompatible blood and blood may ooze from the site of transfusion, from mucous membranes,<sup>321 339</sup> or from the operative site if such exists. Fibrinogen and other labile clotting factors are usually found to be depleted, probably as the result of fibrin formation after liberation of thromboplastic substances from red cells hemolyzed intravascularly.<sup>330</sup> Thrombocytopenia may be present as well.

*Hemoglobinemia* can be detected by examining the blood plasma without delay. Hemoglobinuria and jaundice, as well as oliguria or even anuria, may follow, but hemoglobin may be present only in the first urine specimen passed after the transfusion. Signs of *renal involvement* may develop rapidly and subside in large measure after 24 hours, only to be followed by a progressing state of uremia; or the signs may seem to be insignificant at first and yet are followed by evidence of severe renal impairment. The latter may be succeeded after several days by diuresis and recovery may then occur if proper care has been given (page 483), or uremia may persist.

Death has occurred as late as the seventh to nineteenth day following transfusion, while diuresis and recovery have appeared as late as the sixteenth day.<sup>317</sup>

The mechanism involved in the production of the *renal failure* has been the subject of study for many years. It is clear that hemoglobinemia per se is not the primary cause of the disorder. Injections of hemoglobin into normal animals have not produced hemoglobinuric nephrosis, but when hemoglobin was given intravenously to anesthetized, dehydrated rats, renal ischemia and failure of glomerular filtration developed and were followed by tubular destruction associated with the formation of hemoglobin casts.<sup>322</sup> Focal cortical ischemia has been described.<sup>349</sup> It seems likely that the precipitation of hemoglobin in renal tubules depends upon the functional abnormality of nephrons,<sup>331</sup> which probably is the consequence of circulatory failure associated with transfusion reactions. In addition to the peripheral vascular failure, many other variables contribute to the development of renal failure, including the amount of reduction in urine volume and increased hydrogen ion concentration of the urine. The latter favors the precipitation of hemoglobin in the renal tubules, thereby producing mechanical blockage.

### *Extravascular Hemolysis of Red Cells*

Rh incompatibility is by far the most common cause of transfusion reactions due to extravascular hemolysis. Fortunately anti-Rh antibodies do not occur spontaneously and do not develop in significant titer in every Rh-negative person exposed to Rh-positive blood (Chapter 27).

Of the various components of the Rh-Hr system, anti- $R_h$  (D) is by far the most common antibody causing reactions and anti- $R_h$  plus anti-rh' (CD) is another frequent cause. Anti-hr' (c), anti-rh'' (E), and anti- $R_h$  plus anti-rh'' (anti-DE) are not rare, but other antibodies involving this system are found in less than 1% of the patients having transfusion reactions due to extravascular hemolysis.

In an earlier section, certain Rh alleles for

**Table 11-12. Approximate Relative Frequency of Rh Antibodies**

Fisher Terminology	Wiener Terminology	Approximate Percentage Frequency <sup>56, 63, 187</sup>

\*Some examples reported

which specific antisera have not been found were mentioned (page 460). The antibodies for these antigens seem to be inseparable from certain anti-Rh<sub>0</sub> (D), anti-rh' (C), anti-hr' (c), and anti-rh'' (E) sera,<sup>68</sup> respectively. Of these, the Rh<sub>0</sub> variants (D<sup>u</sup>) appear to be quite important because they are sufficiently antigenic to provoke an immune response, and can give rise to transfusion reactions or

erythroblastosis fetalis; yet, since Rh<sub>0</sub> (D<sup>u</sup>) gives weaker reactions than do other Rh-positive bloods, the blood of an Rh<sub>0</sub> (D<sup>u</sup>) carrier may be mistakenly considered to be Rh negative.<sup>324</sup> Routine use of the antiglobulin technique in typing for Rh antigens can prevent this error. Among the other Rh alleles, anti-rh<sup>w1</sup> (C<sup>w</sup>) and anti-rh<sup>w2</sup> (E<sup>w</sup>) have been known to cause erythroblastosis fetalis.<sup>319</sup>

Table 11-12 indicates that antibodies to Rh-negative blood are not so rare and this should emphasize the fact that the transfusion of Rh-positive patients with Rh-negative blood is potentially dangerous. In a number of patients, transfusion reactions due to this cause have been observed.<sup>68</sup> These have usually been so mild in degree as to be passed off as pyrogenic reactions, but death due to the administration of Rh-negative blood has been reported.

In Table 11-13 the clinical importance of the various blood groups in causing sensitization and transfusion reactions or hemolytic disease of the newborn is indicated. It

**Table 11-13. Blood Groups: Clinical Importance and Sensitivity to Agglutination**

System	Isoantibodies		Components Important in Sensitivity Reactions			Sensitivity to Agglutination by Various Techniques

The blood group systems have been listed in the order of their clinical importance. The order of genetic importance is MNSs, Rh-Hr, ABO and Kidd. Those most readily useful in medicolegal work are ABO, MN and Rh-Hr; other blood factors are rarely or never used.

\*Except during neonatal period

†By no means comparable in frequency with ABO or Rh Hr system

Key to sensitivity ++ indicates preferred technique, + means almost always positive ± may be positive or negative, — almost always negative

is noteworthy how important the Kell factor is from the standpoint of sensitization. Fatal transfusion reactions have been observed.<sup>352</sup> It may be added that a number of the "private" blood group antigens (page 467) also have been associated with hemolytic disease.<sup>68</sup>

The clinical manifestations of extravascular hemolysis (Chapter 20) are less spectacular than those of intravascular red cell destruction. Fever and chills develop frequently but may be delayed in onset for an hour or so. It has been suggested that these febrile reactions are somehow related to splenic sequestration.<sup>56</sup> Acute renal failure is not characteristic of extravascular hemolysis.

#### *Hemolytic Transfusion Reactions in the Absence of Demonstrable Incompatibility*

Several patients have been described in whom transfused red cells were rapidly destroyed even though no antibody was demonstrable at the time of transfusion.<sup>350</sup> In a number of patients, antibody was discovered some days after transfusion or was known to have been present before transfusion.<sup>325</sup> In one subject, however, exhaustive studies failed to reveal an antibody.<sup>371</sup> It may well be that gradually increasing transfusion requirements in patients receiving very many transfusions are due to undetected sensitization. It would be of interest to study such patients by a double-labeling technique<sup>372</sup> in which the suspected incompatible cells would be labeled with <sup>51</sup>Cr and, as a control, the recipient's own cells would be labeled with <sup>42</sup>P.

#### *Delayed Transfusion Reactions*

Delayed transfusion reactions are most commonly due to isoantibodies, such as those directed against Rh-Hr antigens, and may not appear until 2 to 14 days after the transfusion of blood. Two explanations have been offered for this phenomenon.<sup>56</sup> Either antibody is present in the recipient's serum but went undetected because of its low titer, or anti-

body is not detectable by any available method but shows a rapid rise subsequently because the transfusion has triggered a secondary (anamnestic) response. In either instance, hemolysis does not become evident until antibody is produced in sufficient quantity; it may then be very abrupt in onset. To the unwary the eventual development of a positive reaction to a direct Coombs' test in such patients may suggest a diagnosis of autoimmune hemolytic anemia.<sup>306</sup>

#### *Laboratory Investigation of Hemolytic Transfusion Reactions*

Laboratory tests utilized in the investigation of hemolytic transfusion reactions include: (1) those demonstrating red cell destruction, (2) serologic tests to determine the cause of the transfusion reaction, and (3) tests for determining the presence of disseminated intravascular coagulation (Chapter 38). The appropriate investigations have been summarized in Table 11-14.

Hemolysis is evidenced by elevated plasma hemoglobin levels, hemoglobinuria, and hyperbilirubinemia assessed by the indirect technique. Reduced haptoglobin levels indicate intravascular hemolysis; determination of these levels is particularly useful when the

-

reactions are mild. With severe transfusion reactions, methemalbuminemia may also appear. When transfusion reactions are mild, comparison with pre-transfusion pigment values is valuable but is not always possible. It is important to draw blood carefully since artifactually induced hemolysis may make interpretation of data difficult.

Serologic tests include complete retyping of the patient's and donor's blood in an effort to identify the responsible blood group incompatibility. The cross-match should be reconfirmed. In addition, the patient's red cells should be tested for surface immunoglobulin and complement by means of the direct antiglobulin test; the patient's serum should be tested for antibodies against donor cells and the donor's serum should be tested for antibodies that may react with recipient cells.

It is also necessary to examine the administered blood for aerobic and anaerobic bacterial contamination. The urine output should be monitored carefully and the blood should be watched for the development of azotemia.

### Treatment

Since the renal complications are the most lethal, the major aim of therapy must be their prevention and treatment.

PREVENTION depends on the maintenance of renal blood flow. This is accomplished in several ways. (1) Treatment with heparin should be given when intravascular coagulation is present since it probably contributes significantly to the development of renal failure.<sup>360,363</sup> (2) The infusion of the osmotic diuretic mannitol has been recommended as a means of maintaining urine flow, glomerular filtration, and renal blood flow when oliguria is observed.<sup>295</sup> It is customary to give 20 g of mannitol as a 20% solution over a five-minute period. If no urine flow occurs, the initial injection may be repeated, but not more than 80 to 100 g should be used within a 24-hour period. If there is no improvement within 24 hours the trial should be abandoned. Mannitol is contraindicated once acute tubular necrosis has occurred. If

diuresis is induced by mannitol, adequate fluid replacement has to be provided. (3) For patients in shock,  $\alpha$ -adrenergic blocking agents such as phenoxybenzamine may be even more effective than mannitol in increasing renal blood flow,<sup>348</sup> but these experimental agents must only be given by physicians experienced in their use. In animal models, phenoxybenzamine also has been shown to have a beneficial effect in disseminated intravascular coagulation.<sup>344,345</sup> (4) Patients in shock should be treated with compatible transfusions or fluids. If there is any question as to blood compatibility, however, it is best not to give blood; plasma or other fluids should be used instead, for, as has been pointed out (page 482), erroneous conclusions may be reached when blood is examined for antibodies immediately after a transfusion reaction has occurred. (5) On the basis of animal experiments it was concluded that the precipitation of heme pigments in the kidneys is favored by an acid reaction; alkalinization of the urine (4 to 5 g of sodium bicarbonate or lactate given orally or parenterally) was recommended to prevent this. However, once the kidneys have been injured, the value of this procedure may be questioned, since renal ischemia rather than the precipitation of heme pigments in the tubules is probably the principal etiologic factor in the acute renal failure that may follow the transfusion of incompatible blood. Furthermore, the administration of excess sodium salts to patients with severe oliguria presents the double hazard of alkalosis and tetany, in addition to volume overload, congestive heart failure, and pulmonary edema.

The phase of renal insufficiency usually begins about 24 hours after the incompatible blood has been given and may last for many days. During this time it is important (1) not to flog damaged kidneys with diuretics; (2) to limit the fluid intake during this oliguric period to the insensible water loss plus measurable fluid output. Usually 400 to 500 ml per day plus a volume equal to the urinary output will suffice; however, in the presence of fever, diarrhea, vomiting, wound drainage, or other conditions resulting in fluid loss,

replacement of fluid to counteract these losses must also be made; and (3) to maintain adequate nutrition and electrolyte balance. These aims may be accomplished by (a) keeping an accurate record of fluid output and intake and maintaining fluid balance; (b) providing adequate calories by mouth or, if nausea or vomiting supervenes, by giving 50% dextrose in water continuously through a plastic catheter that empties into a large central vein; (c) replacing electrolytes that are lost. The intake should be potassium free. Repeated measurements of electrolytes should be made. Daily electrocardiograms will help in recognizing hyperkalemia. Mild sedation may be required during this period but should be avoided if possible. In critical situations, dialysis with the artificial kidney may be lifesaving.

In the final phase, during the period of tubular recovery and regeneration, there is copious diuresis, resulting in loss of salt and water that must be replaced. Replacement may necessitate the parenteral administration of fluids, but, as recovery takes place, oral administration may suffice.

## 2. Nonhemolytic (Febrile) Transfusion Reactions

Nonhemolytic febrile reactions have been reported in 1 to 20% of patients receiving transfusions, but an incidence of 3 to 4% would be a reasonable estimate for patients in most transfusion centers.<sup>358</sup> These reactions may be due to immune sensitivity to leukocytes, platelets, and various plasma constituents, or they may be due to bacterial and other pyrogens. With the advent of modern transfusion technology the latter have become quite infrequent. Often no cause whatsoever can be discovered.

A chill followed by fever may occur within an hour after the transfusion, or may be delayed for 24 hours. Headache, nausea, and vomiting may accompany this reaction. Often, however, the manifestations are mild and, if fever is the only one, the patient may not even be aware that he is having a reaction. Whatever their degree, febrile reactions usually run their course within a few hours.

*Sensitization to white cell or platelet antigens* is one of the most common causes of nonhemolytic febrile reactions,<sup>299,351,376</sup> especially in patients who have received large numbers of transfusions.<sup>308</sup> Occasionally the reaction may be severe and even life-threatening.<sup>311</sup> In one series of 269 consecutive cases of transfusion reaction, complete leukoagglutinins were found in 58% of patients suffering from chills and fever following a blood transfusion.<sup>321</sup> Such antibodies were found in only 9% of those without these symptoms. The administration of buffy-coat-poor blood may sometimes prevent these reactions (page 477).

Accurate diagnosis depends on the demonstration of antileukocyte antibodies in the recipient, but this information usually is not available when the physician is called upon to differentiate between a hemolytic and a nonhemolytic transfusion reaction. While hemolytic transfusion reactions call for the immediate cessation of the transfusion, nonhemolytic febrile responses are often well tolerated, requiring minimal supportive care usually consisting of antipyretic or antihistamine therapy, if such is not contraindicated (as in thrombocytopenia) (Chapter 35). Antihistamines are most effective if given *before* the transfusion. Unfortunately no foolproof aids to differential diagnosis are yet available and the physician will have to use his best clinical judgment in each case.

A peculiar manifestation of leukoagglutinin transfusion reactions is the appearance of *pulmonary infiltrates*.<sup>375,381</sup> This syndrome is characterized by the sudden onset of chills, fever, tachycardia, a nonproductive cough, and dyspnea. The acute symptoms last for only a few hours, but the pulmonary infiltrates persist for up to 48 hours. Eosinophilia has been noted in several of these patients.

*Plasma sensitivity* has been observed most frequently in patients with hemopoietic disorders who have received multiple transfusions.<sup>305</sup> Chills, fever, backache, pain in the legs, and intestinal peristalsis may occur. Although serologic tests reveal no incompatibility, the plasma rather than other factors may be found responsible if a few milliliters

of plasma, preferably but not necessarily from the donor whose blood is suspected, are injected into the patient. If plasma sensitivity is present, a mild reaction will occur within 30 minutes. The patient's serum should also be examined for antibodies against isologous plasma components. Plasma sensitivity is especially common in persons with paroxysmal nocturnal hemoglobinuria (Chapter 29). In these subjects, the offending plasma factor is heat-labile and can be removed by washing the red corpuscles free of plasma.

A well-defined type of "plasma sensitivity" is due to the presence of anti-IgA antibodies, particularly in patients with IgA deficiency.<sup>364</sup> Patients with this type of allergy may develop a mild reaction characterized by an erythematous rash and urticaria, but they may also develop hypotension and anaphylactic shock. They usually have no fever. Very small amounts of plasma may precipitate the reaction, which is mediated by an IgG antibody that fixes complement and has specificity for IgA. To diagnose this type of hypersensitivity it is usually necessary to demonstrate the presence of anti-IgA and the absence of IgA in the patient's serum. The reaction can be prevented by giving the patient washed red cells (page 477), which will effectively remove a large portion of the offending gamma globulin.

Precipitins reacting with low-density  $\beta$ -lipoproteins have also been found in the sera of patients receiving multiple transfusions.<sup>297</sup>

*Other allergic reactions*, characterized simply by urticaria or occasionally by swelling of lymph nodes and sore throat, eosinophilia, joint pains, and fever, occur in at least 1% of patients having blood transfusions. They may develop during the transfusion or some days later. Angioneurotic edema and asthma have been observed. Some of these reactions are due to the passive transfer of reagins to foods that the patient has eaten or the patient may have reagins for food eaten by the donor. Thus, reactions are less likely if the blood is drawn from donors who have fasted for several hours. These types of reactions respond well to epinephrine or antihistamines.

## Nonimmune Transfusion Reactions

### Circulatory Overload

The administration of excessively large quantities of blood, or smaller amounts given too rapidly ("speed reaction"), can cause circulatory failure, especially when myocardial weakness is present. Circulatory failure is often heralded by the onset of a series of short, sharp coughs, precordial and back pain, dyspnea, cyanosis, and finally a productive cough. The symptoms may develop during or up to 24 hours after transfusion, and death may result from pulmonary edema. Measurement of the patient's venous pressure before transfusion provides a useful guide to the probability of inducing cardiac failure; if the pre-transfusion venous pressure is above normal,<sup>265</sup> transfusion is likely to make the situation worse. When there is any doubt about the patient's cardiovascular status, *continuous central venous pressure monitoring* can be used to signal a dangerous increase in venous pressure. When the central venous pressure is decidedly elevated before the transfusion or rises during the transfusion, blood can only be given safely by the exchange technique (page 477). In patients with no demonstrable failure but a known history of myocardial weakness, overloading of the cardiovascular system can be avoided by transfusing blood from which most of the plasma has been removed, and by giving the blood slowly by the gravity-drip method, with the patient in a propped-up position. The rate of administration should not exceed 2 ml per kg body weight per hour and often may well be slower than this. Only when there has been acute and severe hemorrhage does blood need to be given rapidly.

### Complications Due to Massive Transfusions

With the advent of modern surgical technique and the liberal use of whole blood transfusions, two types of problems have been introduced, ie, metabolic effects result-

ing from the use of large amounts of old "bank blood" and hemorrhagic manifestations.

### Metabolic Effects

The sudden infusion of large volumes of ACD solution may cause hyperkalemia with potassium intoxication and citrate toxicity.<sup>336-340</sup> The potassium is derived from red cells and its concentration in the plasma rises to about 15 to 20 mEq/liter after 10 to 14 days' storage. Because it is metabolized rapidly, citrate rarely accumulates to the point of toxicity in adults unless citrated blood is given with great rapidity or unless the patient has impaired liver function. At citrate concentrations of about 100 mg/dl, tremors may be observed in skeletal muscles and the QT segment of the electrocardiogram is prolonged.<sup>346</sup> At still higher concentrations of citrate, cardiac arrest may develop.

With massive transfusions, ionized calcium is decreased. The intravenous administration of calcium gluconate usually prevents or eliminates the manifestations of citrate toxicity. However, hypocalcemia may not be the only ill effect produced by the infusion of large quantities of citric acid. Blood drawn in ACD solution has a pH of 6.6 on storage as the result of continued glycolysis.<sup>342</sup> Massive transfusions are followed immediately by acidosis, but, in several hours, metabolic alkalosis develops, owing to the metabolic breakdown of sodium citrate.<sup>337</sup> The advantages of CPD as an anticoagulant, as compared with those of ACD, were pointed out earlier (page 474).

### Hemorrhagic Manifestations

The rapid transfusion of large volumes of compatible stored blood may be complicated by a bleeding tendency. Neither platelets nor labile coagulation factors survive well in stored blood, and if the transfusion is equal to the blood volume of the patient, a significant dilutional effect occurs.<sup>321,329,341,384</sup> This may lead to mild thrombocytopenia and minor coagulation abnormalities.

If an incompatible transfusion which results in intravascular hemolysis is given, *diffuse intravascular coagulation* (DIC) may result (Chapter 38). Rare instances of DIC in association with extravascular hemolysis have been reported.<sup>328</sup> A rare complication of transfusion therapy is isoimmune post-transfusion thrombocytopenia.

### Transmission of Infection

*Viral hepatitis* is by far the most common and clinically important infection transmitted by transfusion. The viruses causing hepatitis appear to be hardy and highly infectious. As little as  $\frac{1}{10,000}$  of 1 ml of "icterogenic" plasma injected subcutaneously can cause clinically obvious hepatitis, and as little as  $\frac{1}{10,000,000}$  may lead to serologically detectable evidence of infection.<sup>294</sup> This is why pooled blood products are so dangerous, since virus from a single donor, though diluted, is widely distributed.

The viruses are carried by blood, plasma, albumin, fibrinogen, and AHG preparations, among others,<sup>56,379</sup> and the disease has even been transmitted with topically applied thrombin.<sup>56,379</sup> Gamma globulins prepared either by the Cohn fractionation process or by ether fractionation appear to be free of hepatitis virus.<sup>56</sup>

Two different forms of viral hepatitis that appear to be caused by antigenically different agents have been identified; these can be differentiated by various clinical and, more importantly, serologic criteria. The serologic differentiation was made possible by the discovery of an *antigen* in the blood and tissues of individuals suffering from "serum hepatitis" ("long-incubation hepatitis," MS-2); this antigen is variously referred to as Australia antigen (Aul) or hepatitis-associated antigen (HAA).<sup>295,372</sup> HAA is not found in individuals suffering from "infectious hepatitis" ("short-incubation hepatitis," MS-1).<sup>331</sup> Anti-HAA antibodies also appear in the serum of some patients with serum hepatitis,<sup>313,315</sup> especially on secondary exposure,<sup>334</sup> but never in patients with infectious hepatitis.

Unfortunately both forms of hepatitis can be transmitted by the parenteral (or oral) route and routine testing of donors for HAA will therefore not detect carriers of the infectious hepatitis virus. Nevertheless, all prospective donors must be tested for HAA, since HAA is implicated in 25 to 30% of patients with post-transfusion hepatitis<sup>313,315,374</sup> and rapid techniques for its detection are available.<sup>314,322a,353</sup>

The reported incidence of viral hepatitis following transfusion of blood and blood products varies widely and is influenced by several factors:

1. When the diagnosis is based on clinical evidence such as *icterus*, the reported overall incidence is considerably less than 1% per unit of blood administered,<sup>36,245,318</sup> but it may be in excess of 50% when HAA-positive blood is given.<sup>294</sup> However, when the diagnosis is based on elevated enzyme levels, the incidence is much higher and may reach 3%<sup>315</sup> for recipients of HAA-negative blood and 50% to nearly 100% for recipients of HAA-positive blood.<sup>315,331</sup>

2. Because of the high degree of infectivity of the hepatitis viruses, pooled blood products constitute a particular hazard, especially when materials such as coagulation factors (page 486) are prepared from exceptionally large donor pools.

3. When blood is derived from commercial sources, rather than from volunteer donors, the risks of hepatitis are particularly high. In one study the number of HAA-positive units was 13-fold greater in commercial donor blood than in volunteer blood,<sup>315</sup> and similar differences probably exist for the infectious hepatitis virus for which no specific test is yet available.

4. The incidence of hepatitis also is influenced by the care taken in screening potential donors.<sup>291</sup> Implementation of the following recommendations may aid in reducing the incidence of post-transfusion hepatitis:<sup>374</sup> (a) All prospective donors must be tested for HAA. This technique will detect 25 to 30% of hepatitis carriers. Blood containing anti-HAA antibody is apparently quite safe.<sup>291</sup> (b) It is probably well to select donors from permanent residents of the community. Do-

nors of the skid-row type, donors with tattoos, or those who are known alcoholics and drug addicts, including individuals who *habitually* use marijuana, should be avoided. When blood is obtained from outside suppliers, their standards should be ascertained. All those in close contact with hepatitis patients are excluded from donating blood for six months following contact and should be tested for HAA. Eliminating commercial donors and HAA-positive individuals may decrease the incidence of hepatitis by as much as 95%.<sup>291</sup> (c) It is important that blood banks have information about all cases of clinical hepatitis in their area. If a patient with hepatitis is the recipient of a recent transfusion, all of his donors should be investigated. Abnormal bilirubin and enzyme levels, a positive finding on HAA testing or abnormally high gammaglobulin levels in *unimplicated* donors<sup>296</sup> should lead to their exclusion from donor panels. (d) Since the risk of hepatitis is clearly related to the number of transfusions received, the judicious use of blood and blood products cannot be overemphasized.

It has been suggested that the routine addition of modified gamma globulin to blood may decrease the incidence of post-transfusion hepatitis.<sup>327</sup> Others have shown that gamma globulin from *conventional* sources only neutralizes the infectivity of serum containing the infectious hepatitis virus, but does not consistently ameliorate the infectivity of serum containing the serum hepatitis virus.<sup>331</sup> On the other hand, when gamma globulin is prepared from plasma known to contain anti-HAA antibody, very potent preparations of "SH immune globulin" can be prepared that warrant clinical trials.<sup>355</sup> Encouraging results have already been obtained in the prevention of endemic HAA-positive hepatitis by the prophylactic use of gamma globulin prepared from paid donors<sup>313</sup> known to have a high incidence of anti-HAA antibodies. Such material may also prevent serum hepatitis after accidental inoculation with material containing HAA.<sup>332</sup>

*Other infections transmitted by transfusion* include syphilis,<sup>302,359</sup> malaria,<sup>292,300,303,309</sup> toxoplasmosis,<sup>368</sup> brucellosis,<sup>353</sup> and cytomegalovirus infection.<sup>354</sup> Screening of blood

ing from the use of large amounts of old "bank blood" and hemorrhagic manifestations.

### Metabolic Effects

The sudden infusion of large volumes of ACD solution may cause hyperkalemia with potassium intoxication and citrate toxicity.<sup>336,340</sup> The potassium is derived from red cells and its concentration in the plasma rises to about 15 to 20 mEq/liter after 10 to 14 days' storage. Because it is metabolized rapidly, citrate rarely accumulates to the point of toxicity in adults unless citrated blood is given with great rapidity or unless the patient has impaired liver function. At citrate concentrations of about 100 mg/dl, tremors may be observed in skeletal muscles and the QT segment of the electrocardiogram is prolonged.<sup>276</sup> At still higher concentrations of citrate, cardiac arrest may develop.

With massive transfusions, ionized calcium is decreased. The intravenous administration of calcium gluconate usually prevents or eliminates the manifestations of citrate toxicity. However, hypocalcemia may not be the only ill effect produced by the infusion of large quantities of citric acid. Blood drawn in ACD solution has a pH of 6.6 on storage as the result of continued glycolysis.<sup>312</sup> Massive transfusions are followed immediately by acidosis, but, in several hours, metabolic alkalosis develops, owing to the metabolic breakdown of sodium citrate.<sup>337</sup> The advantages of CPD as an anticoagulant, as compared with those of ACD, were pointed out earlier (page 474).

### Hemorrhagic Manifestations

The rapid transfusion of large volumes of compatible stored blood may be complicated by a bleeding tendency. Neither platelets nor labile coagulation factors survive well in stored blood, and if the transfusion is equal to the blood volume of the patient, a significant dilutional effect occurs.<sup>321,329,341,384</sup> This may lead to mild thrombocytopenia and minor coagulation abnormalities.

If an incompatible transfusion which results in intravascular hemolysis is given, *diffuse intravascular coagulation* (DIC) may result (Chapter 38). Rare instances of DIC in association with extravascular hemolysis have been reported.<sup>328</sup> A rare complication of transfusion therapy is isoimmune post-transfusion thrombocytopenia.

### Transmission of Infection

*Viral hepatitis* is by far the most common and clinically important infection transmitted by transfusion. The viruses causing hepatitis appear to be hardy and highly infectious. As little as  $\frac{1}{10,000}$  of 1 ml of "icterogenic" plasma injected subcutaneously can cause clinically obvious hepatitis, and as little as  $\frac{1}{10,000,000}$  may lead to serologically detectable evidence of infection.<sup>291</sup> This is why pooled blood products are so dangerous, since virus from a single donor, though diluted, is widely distributed.

The viruses are carried by blood, plasma, albumin, fibrinogen, and AHG preparations, among others,<sup>30,379</sup> and the disease has even been transmitted with topically applied thrombin.<sup>26,379</sup> Gamma globulins prepared either by the Cohn fractionation process or by ether fractionation appear to be free of hepatitis virus.<sup>56</sup>

Two different forms of viral hepatitis that appear to be caused by antigenically different agents have been identified; these can be differentiated by various clinical and, more importantly, serologic criteria. The serologic differentiation was made possible by the discovery of an antigen in the blood and tissues of individuals suffering from "serum hepatitis" ("long-incubation hepatitis," MS-2); this antigen is variously referred to as Australia antigen (AuI) or hepatitis-associated antigen (HAA).<sup>293,372</sup> HAA is not found in individuals suffering from "infectious hepatitis" ("short-incubation hepatitis," MS-1).<sup>331</sup> Anti-HAA antibodies also appear in the serum of some patients with serum hepatitis,<sup>313,315</sup> especially on secondary exposure,<sup>334</sup> but never in patients with infectious hepatitis.

Unfortunately both forms of hepatitis can be transmitted by the parenteral (or oral) route and routine testing of donors for HAA will therefore not detect carriers of the infectious hepatitis virus. Nevertheless, all prospective donors must be tested for HAA, since HAA is implicated in 25 to 30% of patients with post-transfusion hepatitis<sup>313,315,374</sup> and rapid techniques for its detection are available.<sup>314,328,353</sup>

The reported incidence of viral hepatitis following transfusion of blood and blood products varies widely and is influenced by several factors:

1. When the diagnosis is based on clinical evidence such as icterus, the reported overall incidence is considerably less than 1% per unit of blood administered,<sup>56,245,318</sup> but it may be in excess of 50% when HAA-positive blood is given.<sup>291</sup> However, when the diagnosis is based on elevated enzyme levels, the incidence is much higher and may reach 3%<sup>315</sup> for recipients of HAA-negative blood and 50% to nearly 100% for recipients of HAA-positive blood.<sup>315,331</sup>

2. Because of the high degree of infectivity of the hepatitis viruses, pooled blood products constitute a particular hazard, especially when materials such as coagulation factors (page 486) are prepared from exceptionally large donor pools.

3. When blood is derived from commercial sources, rather than from volunteer donors, the risks of hepatitis are particularly high. In one study the number of HAA-positive units was 13-fold greater in commercial donor blood than in volunteer blood,<sup>315</sup> and similar differences probably exist for the infectious hepatitis virus for which no specific test is yet available.

4. The incidence of hepatitis also is influenced by the care taken in screening potential donors.<sup>291</sup> Implementation of the following recommendations may aid in reducing the incidence of post-transfusion hepatitis:<sup>374</sup> (a) All prospective donors must be tested for HAA. This technique will detect 25 to 30% of hepatitis carriers. Blood containing anti-HAA antibody is apparently quite safe.<sup>291</sup> (b) It is probably well to select donors from permanent residents of the community. Do-

nors of the skid-row type, donors who or those who are known alcoholics addicts, including individuals who use marihuana, should be avoided; blood is obtained from outside sources; their standards should be ascertained; those in close contact with hepatitis are excluded from donating blood for months following contact and should be tested for HAA. Eliminating commercial and HAA-positive individuals may reduce the incidence of hepatitis by as much as 95%.<sup>291</sup> (c) It is important that blood banks have information about all cases of hepatitis in their area. If a patient with hepatitis is the recipient of a recent transfusion, all of his donors should be investigated for normal bilirubin and enzyme levels, and a positive finding on HAA testing or abnormally high gammaglobulin levels in the donors<sup>296</sup> should lead to their exclusion from donor panels. (d) Since the risk of hepatitis is clearly related to the number of transfusions received, the judicious use of blood products cannot be overemphasized.

It has been suggested that the routine use of modified gamma globulin may decrease the incidence of transfusion hepatitis.<sup>327</sup> Others have found that gamma globulin from commercial sources only neutralizes the infectious hepatitis serum containing the infectious hepatitis virus, but does not consistently ameliorate the infectivity of serum containing the hepatitis virus.<sup>331</sup> On the other hand, gamma globulin is prepared from plasma known to contain anti-HAA antibodies; potent preparations of "SH immune plasma" can be prepared that warrant further trials.<sup>355</sup> Encouraging results have been obtained in the prevention of experimental HAA-positive hepatitis by the prophylactic use of gamma globulin prepared from donors<sup>313</sup> known to have a high incidence of anti-HAA antibodies. Such material may prevent serum hepatitis after accidental contamination with material containing HAA.

Other infections transmitted by transfusion include syphilis,<sup>302,359</sup> malaria,<sup>292,399</sup> toxoplasmosis,<sup>368</sup> brucellosis,<sup>383</sup> and measles virus infection.<sup>354</sup> Screening of

by serologic tests for syphilis is not entirely adequate since in the most infectious phase of the disease (late primary, early secondary) the reactions are negative. *Treponema pallidum* is destroyed, however, if blood is kept at refrigerator temperatures for 96 hours.<sup>377</sup> Plasmodia can survive refrigeration and storage. Prophylactic treatment of donors with antimalarials is sometimes practiced in countries where malaria is endemic.

Another serious, although fortunately uncommon, hazard is from the administration of contaminated blood. This is due to the accidental introduction of saprophytic bacteria into the bottle of blood. Gram-positive saprophytes, such as diphtheroids, generally produce only fever. However, gram-negative bacteria have been responsible for the production of profound shock that is almost always fatal.<sup>378</sup> Many gram-negative bacteria appear to be capable of utilizing citrate as the sole source of carbon and can multiply in the refrigerator at 4 to 8° C. *Pseudomonas* is one of the most common offenders. The coli-acrogenes variety exhibits good growth in the incubator and at room temperature but not always in the refrigerator. After a latent period of 30 minutes or more, fever, hypotension, and pain in the abdomen and extremities develop and death from shock may take place within six hours. Severe vomiting and diarrhea occur and, if the patient survives for 24 hours, signs of renal failure develop. A hemorrhagic diathesis may ensue. Differentiation from a reaction due to the administration of incompatible blood can be made by microscopic examination of a gram stain of blood remaining in the bottle and by the absence of evidence of a hemolytic reaction. Antibiotics are of limited or no value as prophylactic additives to the blood.

### Miscellaneous III Effects

*Thrombophlebitis* is not rare when transfusions are given repeatedly and especially if polyethylene catheters or small veins are used, particularly in the lower extremities.

*Hemosiderosis* closely resembling hemo-

chromatosis may result from the administration of a large number of transfusions.

*Fat embolism* may occur if positive pressure is used when blood is being given via the bone marrow or in patients who have bony injuries. Secondary osteomyelitis or mediastinitis and cardiac tamponade can follow such transfusions. *Air embolism*, resulting from the accidental introduction of air as, for example, through ill-fitting tubing or when blood is introduced under pressure, is usually well tolerated if the amount is small (<30 ml) but may be dangerous in a gravely ill patient.

## Clinical Use of Plasma and Plasma Derivatives

The large-scale use of plasma began during World War II when plasma was introduced as a volume expander in the treatment of shock under field conditions. Plasma is still given as a volume expander, but now its value as a source of special fractions, such as clotting factors, albumin, and gamma globulins, far outstrips all other uses. The role of plasma derivatives in the therapy of disease will be discussed elsewhere in the appropriate clinical context; this section is intended as a general introduction to the clinical use of plasma and plasma derivatives.

### Plasma

**COLLECTION.** Plasma is generally prepared from single-donor units of fresh blood after the cellular elements have been removed for use in transfusion. Other sources include outdated blood and plasmapheresis of volunteer donors, usually for the preparation of special plasma derivatives.<sup>413</sup> In plasmapheresis<sup>401</sup> a unit of blood is removed at a time from the donor and centrifuged. The supernatant plasma is separated and the packed cells are reinfused in the donor immediately. In this way two units are readily processed at one time and the same procedure may be repeated twice weekly without changing the plasma protein patterns of the donor to any extent.<sup>414</sup> Even larger volumes

of plasma may be obtained by continuous flow centrifugation techniques.<sup>387,402a</sup>

**STORAGE.** Since plasma is usually a by-product of blood transfusion, it contains ACD or CPD anticoagulant (page 473). EDTA or citrate formulas without dextrose may be used if blood is collected specifically for plasma fractionation. Heparin is not a suitable anticoagulant if the plasma is to be stored for more than two days.

Storage conditions depend on the projected use of the product. When plasma is to be used as a volume expander or as a source of albumin it may be stored at 15 to 30° C up to three years.<sup>421</sup> Albumin is stable under these conditions, although most coagulation factors deteriorate rapidly. In addition, fibrin degradation products (Chapter 38) that induce hemostatic defects following transfusion may develop.<sup>398</sup> If plasma is to be used for replacement therapy in disorders of coagulation, it must be frozen or freeze-dried within a few hours of collection.<sup>421</sup>

**INDICATIONS.** In the past, plasma has been used mainly as a volume expander, but for patients in acute traumatic shock whole blood is usually the therapy of choice (page 475); Ringer's lactate<sup>406</sup> or other plasma expanders such as dextran, plasma protein fraction (PPF), or albumin (see below) may be equally effective in an emergency. Plasma, PPF, or albumin is also indicated in the therapy of burns.

Fresh-frozen or freeze-dried plasma is a useful source of coagulation factors including factors V and VIII. Other factors such as I, II, VII, IX, X, XI, XII, and XIII may be obtained in somewhat reduced quantities from outdated blood stored at 4° C, although fresh-frozen plasma is usually preferable (see Chapter 37 for details).

Plasma also has been used in the therapy of hypogammaglobulinemia (Chapter 44) and as a source of CI-esterase inhibitor in the treatment of hereditary angioneurotic edema.<sup>388</sup>

**COMPLICATIONS.** The complications of plasma therapy are similar to those of whole

blood transfusion. They include (1) allergic reactions to white cell and platelet antigens or gamma globulin components<sup>304,364,391</sup>; (2) citrate toxicity (page 486); (3) bacterial contamination; and (4) hepatitis. The last-named probably is the most serious complication and adequate precautions (page 487) need to be taken. Pooled plasma should never be used. Whenever possible, plasma fractions should be given, rather than whole plasma since the hepatitis-associated antigen is probably removed in their preparation.<sup>56</sup>

### Plasma Fractions

The traditional cold ethanol method developed by Cohn during World War II is still the basis for plasma fractionation in the United States.<sup>389,409,413</sup> The procedure is based on the fractional precipitation of plasma proteins with ethanol at low temperatures and low salt concentrations. Proper sequential adjustment of the concentration of protein salts and ethanol as well as of temperature and pH permits the isolation of six fractions, each of which can be subfractionated by appropriate procedures into relatively pure components. Other fractionation schemes utilize ether,<sup>410</sup> polyphosphates,<sup>408</sup> combinations of ammonium sulfate and Rivanol,<sup>396</sup> and polyethylene glycol or glycine.<sup>410</sup> Still other methods employ specific adsorbants such as cellulose derivatives.<sup>416,417</sup> Immunoabsorbants are under investigation for the preparation of purified antibodies to diphtheria, tetanus, and other bacterial infections.<sup>413</sup>

### Albumin Preparations

Solutions rich in albumin can be produced by a variety of techniques,<sup>389,408</sup> but that produced by alcohol fractionation tends to be the purest (>95% albumin). The material may be heated to 60° C for 10 hours to prevent the transmission of hepatitis.<sup>392</sup> In a less elaborate variation of this method a preparation containing 85 to 90% albumin may be prepared (plasma protein fraction, PPF); this is as useful clinically as the more expensive

product of the original Cohn method.<sup>397, 403, 419</sup> It too can be heated to destroy the hepatitis virus.

Albumin has been used in the treatment of patients in shock due to hemorrhage, trauma, or burns,<sup>391, 399</sup> and for the therapy of patients with hypoalbuminemia due to cirrhosis or chronic renal disease. In the latter group, it may be of little permanent value, since it is often excreted as quickly as it is infused.

Albumin and PPF are marketed as 5 g/dl solutions.<sup>420</sup> This concentration is most frequently used as a plasma expander. Twenty-five grams of albumin are the osmotic equivalent of about 500 ml (5 dl) of plasma. Albumin also comes in a 25 g/dl solution that is low in sodium and is particularly useful in the treatment of patients with protein-deficiency states and burns. It should not be given to dehydrated patients without the concomitant infusion of other fluids.

### *Immunoglobulins*

Immunoglobulins may be prepared by cold ethanol fractionation,<sup>489</sup> by ether fractionation,<sup>407</sup> or by precipitation with ammonium sulfate. The cold ethanol method yields about 95% IgG with little IgA or IgM.<sup>396</sup> The preparation is marketed as a 16 g/dl solution,<sup>420</sup> representing a 16-fold concentration of plasma IgG. It should always be given intramuscularly since adverse reactions are encountered when it is given by the intravenous route.<sup>386</sup> These reactions are thought to be due to aggregates and can be prevented by the use of immunoglobulin preparations treated with proteolytic enzymes<sup>386, 412</sup> or incubated at a low pH.<sup>386</sup> The biologic half-life of such preparations is decreased, however.<sup>402, 405</sup>

Specific immunoglobulins against a number of infectious agents are available and others are being developed.<sup>411</sup> Anti-Rh<sub>0</sub> globulin is discussed in Chapter 27.

Various investigations have shown that IgA and IgM globulins differ from IgG in regard

to the antibodies that they contain.<sup>404, 418</sup> Immunoglobulin preparations containing from 15 to 20% each of IgA and IgM globulins are now available.<sup>411</sup>

The use of immunoglobulins in patients with immune deficiency syndromes is discussed in Chapter 44. Generally 100 to 300 mg/kg are given prophylactically every three to four weeks, so as to assure a minimum circulating IgG level of no less than 200 mg/dl. *Prophylactic therapy* is particularly useful in patients with sex-linked congenital agammaglobulinemia, transient hypogammaglobulinemia of childhood, late-onset agammaglobulinemia, and agammaglobulinemia with thymoma. Surface infections involving the respiratory tract and the intestinal tract are not prevented by this therapy. During *acute infections* of other kinds it is well to give additional injections of 200 to 300 mg/kg.

The role of gamma globulin in the prevention of hepatitis has been discussed previously (page 487).

### *Clotting Factors*

The preparation of clotting factors and their use in the therapy of coagulation disorders are discussed in Chapters 37 and 38.

### *Plasma Enzymes and Enzyme Inhibitors*

At least four plasma enzymes and enzyme inhibitors have been isolated, although their clinical application is still in the investigational stage.<sup>411</sup> Plasminogen has been tried in the therapy of patients with hyaline membrane disease<sup>400</sup>; serum cholinesterase may be useful in the therapy of persons who have taken overdoses of succinylcholine<sup>390</sup> and of those poisoned by alkyl phosphates.<sup>393</sup> Cl-esterase inhibitor may be lifesaving in patients suffering from hereditary angioneurotic edema.<sup>411</sup> Antithrombin III (Chapter 38) is being tried in the therapy of intravascular coagulation.<sup>411</sup>

but the transfusion of granulocytes and lymphocytes must still be regarded as experimental and is for the most part restricted to special centers.

The transfusion of leukocytes and platelets is complicated by the existence of antigens other than the blood group determinants discussed in the previous chapter. Exposure to foreign antigens of this type evokes the production of powerful antibodies that may render useless the transfusion of platelets or leukocytes carrying the corresponding determinants.

## **Leukocyte Antigens**

### **History**

Research on leukocyte antigens and organ transplantation has been inextricably intertwined and rightly so, because, with rare exceptions, most presently recognized leukocyte antigens are also found on other tissues, where they act as major determinants of the success or failure of tissue transplants. Thus the terms "leukocyte antigens," "transplantation antigens," and "histocompatibility antigens" are used interchangeably. The first proof that leukocytes carry transplantation antigens was provided by Medawar, who, in 1946, showed that graft rejection is an immunologic phenomenon and that a state of homograft sensitivity can be induced by an

THE need for effective transfusion of platelets and leukocytes has long been recognized, but the techniques for collecting and transfusing these blood components in a viable state have developed much more slowly than those for red cells. Platelet transfusions are now available in most hospitals,

intradermal injection of leukocytes.<sup>69</sup> Similar observations have since been made in many species including man.<sup>37,91</sup> Conversely, it was also shown that antileukocyte antibodies appear after tissue transplantation in animals and man,<sup>3,135</sup> again suggesting that histocompatibility testing is almost synonymous with leukocyte grouping.

The systematic study of leukocyte antigens in man began in 1954; Dausset, in a study of 60 persons with leukoagglutinating antibodies, found that 90% of these individuals had received multiple transfusions.<sup>23</sup> Other studies confirmed the role of transfusion in the induction of antileukocyte isoantibodies<sup>71,89</sup> and showed that isoantibodies against leukocytes may also appear during pregnancy,<sup>87,101</sup> the latter being formed against fetal leukocyte antigens inherited from the father.

In 1958, Dausset observed that six individuals who had received multiple small transfusions from a single donor all showed a similar pattern of reactivity against a panel of foreign leukocytes.<sup>24</sup> He concluded that these individuals lacked the same antigen, which he named Mac. About 60% of the French population possess this antigen, now referred to as HL-A2. An antigen identical to Mac and three other antigens were described by Killman in 1958<sup>53</sup> and in 1959 Van Rood and associates identified two new antigens, 2 and 3, by the use of leukocyte agglutinins formed after pregnancy.<sup>102</sup>

Van Rood and Eernisse,<sup>97</sup> in describing the first leukocyte group system, showed that the antigens 4a and 4b (leukocyte Group Four) behaved as if they were determined by alleles. Family studies subsequently confirmed this conclusion and indicated that the 4a and 4b genes are inherited as simple codominant mendelian characters.<sup>99</sup> Subsequently, many other leukocyte groups were described and designated by a confusing array of letters and numerals: Group Five (5a and 5b), Group Six (6a and 6b), Group Seven (7a, 7b, 7c, 7d), Eight (8a) and Nine (9a) by van Rood and coworkers<sup>100,103</sup>; PI<sup>a</sup>GrLy<sup>b1</sup> and PI<sup>a</sup>GrLy<sup>c1</sup> by Shulman and associates<sup>114</sup>; LA1 and LA2 by Payne and colleagues<sup>88</sup>; and LA3 by

Bodmer and coworkers<sup>15</sup>; the Hu-1 system by Dausset.<sup>24</sup>

Histocompatibility workshops in 1965 (Leyden)<sup>45</sup> and in 1967 (Torino)<sup>46</sup> clearly established that most of the leukocyte antigens defined by the sera of 16 participating laboratories were determined by closely linked genes at one chromosomal region, which was called the HL-A locus<sup>19,46,105</sup> (Human Leukocyte, locus A<sup>54</sup>). At the same time a new system of designations was recommended by which a well-defined factor would be indicated by a number following the symbol for the system, such as HL-A1, HL-A2, HL-A6, etc.<sup>80</sup> When a factor is confirmed by several laboratories but does not yet qualify for an HL-A designation, it is given a provisional number preceded by the prefix W, eg W21.<sup>141</sup> Specificities discovered by individual laboratories carry designations identifying the laboratory of origin, eg Te6 (Terasaki, Table 12-1). Such specificities may eventually be elevated to W or HL-A status. The current series of recognized HL-A antigens and the corresponding older designations used in various laboratories are given in Table 12-1.

## The HL-A System

### Genetics

The major antigens found on human leukocytes are determined by a single chromosomal segment, the "major histocompatibility complex" (MHC) which is situated on an as yet unidentified pair of autosomes. Those portions of the MHC which determine the major serologically defined histocompatibility antigens of man have been named the HL-A loci.<sup>80</sup> Two closely linked loci are presently well defined and are referred to as the LA locus and the Four locus. Additional loci may exist,<sup>54</sup> but this has been denied by some researchers. Each of the two major loci is characterized by an as yet unknown number of genes that behave as multiple alleles, since only one LA allele and one Four allele is present on each of a pair of chromosomes. The antigens presently known to be products

but the transfusion of granulocytes and lymphocytes must still be regarded as experimental and is for the most part restricted to special centers.

The transfusion of leukocytes and platelets is complicated by the existence of antigens other than the blood group determinants discussed in the previous chapter. Exposure to foreign antigens of this type evokes the production of powerful antibodies that may render useless the transfusion of platelets or leukocytes carrying the corresponding determinants.

## Leukocyte Antigens

### History

Research on leukocyte antigens and organ transplantation has been inextricably intertwined and rightly so, because, with rare exceptions, most presently recognized leukocyte antigens are also found on other tissues, where they act as major determinants of the success or failure of tissue transplants. Thus the terms "leukocyte antigens," "transplantation antigens," and "histocompatibility antigens" are used interchangeably. The first proof that leukocytes carry transplantation antigens was provided by Medawar, who, in 1946, showed that graft rejection is an immunologic phenomenon and that a state of homograft sensitivity can be induced by an

THE need for effective transfusion of platelets and leukocytes has long been recognized, but the techniques for collecting and transfusing these blood components in a viable state have developed much more slowly than those for red cells. Platelet transfusions are now available in most hospitals,

intra-dermal injection of leukocytes.<sup>69</sup> Similar observations have since been made in many species including man.<sup>37,91</sup> Conversely, it was also shown that antileukocyte antibodies appear after tissue transplantation in animals and man,<sup>3,123</sup> again suggesting that histocompatibility testing is almost synonymous with leukocyte grouping.

The systematic study of leukocyte antigens in man began in 1954; Dausset, in a study of 60 persons with leucoagglutinating antibodies, found that 90% of these individuals had received multiple transfusions.<sup>23</sup> Other studies confirmed the role of transfusion in the induction of antileukocyte isoantibodies<sup>71,86</sup> and showed that isoantibodies against leukocytes may also appear during pregnancy,<sup>87,101</sup> the latter being formed against fetal leukocyte antigens inherited from the father.

In 1958, Dausset observed that six individuals who had received multiple small transfusions from a single donor all showed a similar pattern of reactivity against a panel of foreign leukocytes.<sup>21</sup> He concluded that these individuals lacked the same antigen, which he named Mac. About 60% of the French population possess this antigen, now referred to as HL-A2. An antigen identical to Mac and three other antigens were described by Killion in 1958<sup>53</sup> and in 1959 Van Rood and associates identified two new antigens, 2 and 3, by the use of leukocyte agglutinins formed after pregnancy.<sup>102</sup>

Van Rood and Eernisse,<sup>97</sup> in describing the first leukocyte group system, showed that the antigens 4a and 4b (leukocyte Group Four) behaved as if they were determined by alleles. Family studies subsequently confirmed this conclusion and indicated that the 4a and 4b genes are inherited as simple codominant mendelian characters.<sup>99</sup> Subsequently, many other leukocyte groups were described and designated by a confusing array of letters and numerals: Group Five (5a and 5b), Group Six (6a and 6b), Group Seven (7a, 7b, 7c, 7d), Eight (8a) and Nine (9a) by van Rood and coworkers<sup>100,103</sup>; P1GrLy<sup>B1</sup> and P1GrLy<sup>G1</sup> by Shulman and associates<sup>114</sup>; LA1 and LA2 by Payne and colleagues<sup>88</sup>; and LA3 by

Bodmer and coworkers<sup>15</sup>; the Hu-1 system by Dausset.<sup>24</sup>

Histocompatibility workshops in 1965 (Leyden)<sup>15</sup> and in 1967 (Torino)<sup>16</sup> clearly established that most of the leukocyte antigens defined by the sera of 16 participating laboratories were determined by closely linked genes at one chromosomal region, which was called the HL-A locus<sup>19,16,105</sup> (Human Leukocyte, locus A<sup>54</sup>). At the same time a new system of designations was recommended by which a well-defined factor would be indicated by a number following the symbol for the system, such as HL-A1, HL-A2, HL-A6, etc.<sup>60</sup> When a factor is confirmed by several laboratories but does not yet qualify for an HL-A designation, it is given a provisional number preceded by the prefix W, eg W21.<sup>141</sup> Specificities discovered by individual laboratories carry designations identifying the laboratory of origin, eg Te6 (Terasaki, Table 12-1). Such specificities may eventually be elevated to W or HL-A status. The current series of recognized HL-A antigens and the corresponding older designations used in various laboratories are given in Table 12-1.

Note The specificities listed under HL-A designations eg W 23 and W 24 under HL-A 9 indicate subfactors which are part of the broader HL-A specificity

of these two segregant series of genes are listed in Table 12-1. The First or LA series contains HL-A 1,2,3,9,10, 11, and some antigens not yet designated by the HL-A nomenclature. The Second "Four" series contains the HL-A 5,7,8,12, and 13 antigens as well as others. The genetic determinants within each series behave as mutually exclusive genes or alleles. Thus a given person may have a maximum of two first series and two Second series antigens, one First series and one Second series antigen being determined by each chromosome. The antigens determined by the same chromosome are referred to as *haplotypes*.

The LA and Four loci appear to be situated very close to each other within the MHC, since very few recombinations have been described.<sup>54</sup> Because of this close linkage the antigens defined by a single chromosome are inherited as units or "packets." Thus only four types of children can result from any given marriage (Fig. 12-1). No parent has yet been found to hand down two antigens belonging to the same series to his

children. If, for instance, one of the parents possesses antigens HL-A1 and HL-A2 (both from the First series) and the other one does not, the children always receive either HL-A1 or HL-A2, but never both.

The gene frequencies for several U.S. population groups are given in Table 12-2. If there were no association between individual First and Second series determinants, the frequency of each haplotype would, of course, depend only on the gene frequencies of the individual alleles. It has been shown, however, that some haplotypes occur much more frequently than others. Among Caucasians the strongest association is HL-A1, 8 and HL-A3, 7, but others have also been described.<sup>49,121</sup> The cause of this phenomenon is unknown.

Racial differences in HL-A antigens have been noted and may in the future serve as useful anthropologic markers.<sup>48</sup> Thus HL-A1 may be a unique characteristic of Caucasian populations,<sup>15</sup> since it appears to be absent among Japanese,<sup>114</sup> Australian aborigines,<sup>54</sup> pygmies,<sup>15</sup> and American Indians,<sup>14</sup> and is

Fig. 12-1 The inheritance of HL-A antigens. The letters a b and c d designate paternal and maternal chromosomes respectively and the numbers refer to HLA antigens. The specificities determined by any given chromosome are referred to as haplotypes and are inherited as units.

Table 12-2. HL-A Gene Frequencies in Three Population Groups

\*Te 11

After Albert et al. *Histocompatibility Testing* 1970<sup>47</sup>

present in a much lower frequency in American Negroes and Maoris than in Caucasians.<sup>15</sup> In addition, the observed associations of HL-A1, HL-A8 and HL-A3, HL-A7 among Caucasians do not show up in other populations.

HL-A8 is of low frequency in Japanese; HL-A10 is of higher frequency among Orientals and Negroes than among Caucasians<sup>118</sup>; and Te10 is common among Orientals. Pygmies also have a much higher incidence of "blank" alleles in both series of antigens than do Caucasians.<sup>15</sup>

In Greenland Eskimos there is a very high incidence of HL-A9 (81%), FJH (38%), and HL-A5. The latter is four times as common among Eskimos as among Northern Europeans, but HL-A1, HL-A8, Da 17, LI, HL-A7, HL-A10, and SL are of very low frequency.<sup>54</sup>

In addition to the two HL-A loci, the major histocompatibility complex contains regions that determine other aspects of lymphocyte structure and function. One of these is the MLC (mixed leukocyte culture) or MLR (mixed leukocyte reaction) locus,<sup>83,27,142</sup> which is closely linked to the HL-A "Four" region of the chromosome and whose products are responsible for the strong stimulation of lymphocytes in mixed leukocyte cultures (Chapter 7 and below) *in vitro*, and the graft-versus-host (GvH) response (Chapter 7) *in vivo*.<sup>83,27,73a,142</sup> In mice the GvH reaction as well as the MLC reaction is directed against the products of immune response (Ir) genes, which are also closely linked to the H-2K locus (comparable to the

Four locus in man) and which control the immune response to a large number of antigens.<sup>13a,55</sup> HL-A associated Ir genes may also occur in man,<sup>18</sup> but their relation to the MLC locus is not yet established. The lymphocyte-stimulating antigens appear to be present in T cells (Chapter 7) only, since lymphocytes from patients with thymic dysplasia (Nezeloff's syndrome, Chapter 44), though carrying HL-A antigens, do not stimulate lymphocytes of HL-A nonidentical individuals.<sup>27</sup> Experiments in rodents have also confirmed the thymus dependence of stimulating lymphocytes<sup>27</sup> and the expression of immune response (Ir) genes in thymus derived cells.<sup>13a</sup>

### Methods of Detection

Many methods have been introduced for the detection of leukocyte antigens<sup>54</sup> including: (1) leucoagglutination techniques; (2) cytotoxicity tests, which depend on the complement-dependent disruption of the cell membrane and the demonstration of cell death by phase contrast microscopy, penetration of the cell membrane by supravital dyes, fluorochromasia, and <sup>51</sup>chromium release; (3) complement-fixation tests. Reviews of all of these techniques and detailed notes of methodology have been published.<sup>54,79</sup> All of these tests are macrotechniques that require relatively large quantities of cells and sera, measured in millions of cells and drops of sera. Reliable and simple microcytotoxicity tests are less demanding of resources and personnel.<sup>72,123</sup> These tests can be performed with

1  $\mu$ l (or less) of antiserum and 2,000 to 3,000 cells; following an appropriate incubation period, 5  $\mu$ l of rabbit complement are added and, after further incubation, cytotoxicity is detected by one of several means, usually the uptake of a supravital dye such as trypan blue or eosin Y<sup>54</sup> (Fig. 12-2). Since platelets also contain HL-A antigens (see below), they may be used instead of lymphocytes in HL-A typing. Details of this technique are discussed on page 514.

Theoretically, typing sera could be derived from polytransfused patients, from individuals who have received organ transplants, and from animals such as chimpanzees that have been deliberately immunized with human transplantation antigens.<sup>51</sup> The most satisfactory sources of typing sera, however, are pregnant women and human volunteers who have been deliberately sensitized with foreign skin grafts and/or leukocytes.<sup>54</sup> The antibodies are frequently of rather limited specificity, since sensitization, either natural or planned, usually involves a restricted number of leukocyte antigens, eg, the antigens that a fetus has inherited from the father and that differ from those of the mother.

*Cytotoxic antibodies* may be either IgG or IgM,<sup>54 87 119,136</sup> although IgG antibodies appear to be the most common. Monospecificity of typing sera is highly desirable and could be established, in an operational sense at least, by population and family studies<sup>54</sup> as well as by absorption techniques.<sup>137</sup> However, since many sera contain cross-reacting antibodies that may be removed by absorption with either of two antigens,<sup>54</sup> absorption studies by themselves are not sufficient proof of monospecificity. Cross reactivity appears to be confined to antigens within a series,<sup>54</sup> suggesting that greater structural differences exist between antigens belonging to the two series than between antigens within a series.

#### **Correlation between HL-A Typing and Mixed Leukocyte Cultures (MLC)**

When lymphocytes from unrelated individuals are mixed and allowed to grow *in vitro*, enlargement, DNA synthesis, and cell

division take place, apparently reflecting a primary immune response stimulated *in vitro*. In this system, lymphocytes function not only as mediators of immunity but also as carriers of antigens. It appears that differences at major histocompatibility loci usually correlate well with the immunologic reactivity in mixed leukocyte cultures,<sup>1-4</sup> although mixed lymphocyte reactivity is now known to be governed by a locus that lies on the same chromosome as the *major* (Four and LA) loci, but is separate from them (see above).<sup>8a,27,35</sup> Generally speaking, clinical trials have shown good correlation between the results of lymphocyte typing, mixed leukocyte cultures, and the survival of allografts.<sup>8,21</sup>

The MLC test also lends itself to some quantitative evaluation of HL-A differences. This is most clearly seen in sibling studies in which individuals with identical haplotypes show no stimulation; those differing by two haplotypes exhibit maximum stimulation and those differing by a single haplotype show an intermediate degree of stimulation.<sup>1,112</sup>

Descriptions of standard methods for mixed leukocyte cultures have been published.<sup>8,9</sup> Most MLCs are now done by the one-way test in which one population of cells is pretreated with mitomycin. This population then serves as the antigen, whereas the other population furnishes the proliferating cells.<sup>9</sup> A speeded-up version of the test has also been described.<sup>11</sup>

#### **Chemical Characterization of HL-A Antigens<sup>37,94</sup>**

Unlike ABH and Lewis blood group substances, HL-A antigens are not found in secretions and the extraction of antigen from cell membranes is therefore a necessary first step in their characterization. Several methods have been described<sup>26,52 68</sup> and separation of series 1 and 2 antigens has been achieved.<sup>66</sup> Highly purified HL-A antigens have a sedimentation coefficient  $S_{20}W$  of 2.3 and a molecular weight of 31,000 daltons.

**Fig 12-2** The microcytotoxicity test. A, A negative reaction with living lymphocytes (only one stained lymphocyte seen). B, A weakly positive reaction with killing of half the cells. C, A strongly positive reaction with killing and staining of all lymphocytes. (From Kissmeyer-Nielsen and Thorsby,<sup>24</sup> courtesy of the authors and Transplantation Reviews.)

HL-A antigens are essentially polypeptide in nature<sup>78,94</sup>; antigenic activity is irreversibly destroyed by proteolytic enzymes, a variety of protein denaturants, temperatures in excess of 50°C, pH values above 10 and below 4, and detergents in concentrations sufficient to irreversibly affect protein conformation. In addition, distinct, reproducible,

and statistically significant differences in amino acid composition have been demonstrated in HL-A and H-2 antigens of different phenotypes.<sup>78-94</sup> Carbohydrates make up less than 1% of highly purified HL-A antigens. It is unlikely that carbohydrates are essential for antigenic activity *in vivo*, but this cannot be ruled out with . . .

## Distribution of HL-A Antigens

HL-A antigens have been found on both lymphocytes and granulocytes,<sup>11,116</sup> but there appear to be fewer on granulocytes than on lymphocytes.<sup>130</sup> HL-A antigens are also found on leukemic leukocytes.<sup>131</sup> No HL-A antigens have been detected on mature red cells so far,<sup>109</sup> although the Bg<sup>a</sup> antigen, which is related to HL-A7, may be an exception.<sup>74</sup> Reticulocytes appear to possess HL-A antigens<sup>44</sup> that presumably are lost or "switched off" during maturation of the cell. Mature red cells do, however, contain other transplantation antigens, notably those belonging to the ABO system. HL-A antigens are well represented on platelets (page 511).<sup>120</sup>

HL-A antigens also appear to be constituents of most normal human tissues. Those tested include skin,<sup>70</sup> kidney,<sup>70</sup> liver,<sup>106</sup> lung,<sup>106</sup> placenta,<sup>106</sup> and spermatozoa<sup>33</sup> in which a probable haploid expression has been demonstrated. HL-A antigens are also detectable on various tissue culture lines.<sup>93</sup>

## Non-HL-A Leukocyte Antigens

Non-HL-A leukocyte antigens found on leukocytes include determinants of the ABO system<sup>34</sup> as well as the antigens NA1, NB1, and Vaz, 5a/5b and 9a. The ABH determinants have been discussed in Chapter 11. The NA1,<sup>58</sup> NB1,<sup>57</sup> and Vaz<sup>59</sup> antigens are of particular interest since they appear to be granulocyte specific. They segregate independently of the HL-A antigens. Antibodies against the latter antigens may lead to neonatal granulocytopenia<sup>57,58,59</sup> (Chapter 42).

The diallelic antigens 5a and 5b<sup>62</sup> have a gene frequency of .20 and .80, respectively. Anti-5b sera are quite common, but anti-5a sera are rare<sup>61</sup>; both sera give agglutination reactions only.<sup>61</sup> The 5a/5b antigens do not share the HL-A locus and do not appear to function as transplantation antigens.<sup>124</sup>

The 9A antigen, also described by van Rood, apparently is not associated with any of the other antigens.<sup>124</sup>

## Clinical Significance of Leukocyte Antigens

### Transplantation

A large body of evidence now indicates that the survival and function of tissue transplants are noticeably affected by the degree of donor-recipient compatibility within the HL-A system<sup>34</sup> especially at the Four locus.<sup>107</sup> For while the activation of lymphocytes in MLC is dependent on incompatibilities determined by non-HL-A loci (above), the destruction of target cells in sensitized individuals appears to be mediated by cells and/or antibodies with specificity for HL-A antigens.<sup>27,73a</sup> At the same time it is obvious that other tissue antigens also function as transplantation antigens, notably those belonging to the ABO system (Chapter 11), and, probably, a large number of "minor" histocompatibility antigens whose identity is not yet established, but whose combined importance may rank with that of any one HL-A antigen.

The survival time of *skin transplants* is definitely affected by the compatibility of HL-A antigens,<sup>3,54,104,112,138</sup> although in most studies this correlation is only noted when transplants are exchanged between related pairs.<sup>20,104,138</sup> Nevertheless, leukocyte typing appears to be useful when skin grafts are selected for patients suffering from severe burns; skin from closely matched unrelated donors shows much better survival than that from poorly matched donors.<sup>13</sup> However, even in HL-A and ABO identical siblings, skin transplants seldom survive more than twice as long as those from incompatible donors, which clearly indicates that antigens other than those belonging to the HL-A and ABO systems also are important in skin transplantation. The degree of stimulation in mixed leukocyte cultures appears to be a good prognosticator of the fate of skin transplants in nonsensitized individuals, but is probably of little value in sensitized pa-

tients.<sup>107</sup> Others have found no correlation between MLC responses and skin-graft survival.<sup>112</sup>

The survival and function of *kidney transplants* also depend on the goodness of the histocompatibility match.<sup>51,131</sup> Results are universally satisfactory when HL-A identical siblings are used as donors,<sup>54,56</sup> and good results also are obtained when the recipient has one or two antigens not present in the donor. The course of mismatched transplants, when the donor has one or two antigens not present in the recipient, is much less satisfactory, irrespective of whether the donor is a sibling, parent, or unrelated individual.<sup>54,56</sup> The survival of kidneys from closely matched unrelated donors (cadaver transplants) is also better than that from poorly matched donors.<sup>82</sup> The presence of preformed antileukocyte antibodies in the recipient indicates a poor prognosis for kidney survival, even when donors and recipients are well matched.<sup>83</sup> The data for *heart transplants* are sparse, but suggest that similar relationships between prognosis and the goodness of the match exist.<sup>54</sup>

*Bone marrow transplants* (Chapter 44) present special problems since they involve the transfer of immunologically competent cells into an immunologically crippled host. When histocompatibility differences exist, graft-versus-host (GvH) disease (Chapter 7) complicates the course of almost all patients and the host-versus-graft response (homo-graft rejection, Chapter 7) often results in transplant failure. GvH disease is characterized by dermatitis, hepatitis, hemolytic anemia, and thrombocytopenia, and eventually by a severe wasting syndrome, bone marrow aplasia, lymphatic depletion, infections, and death.<sup>42,67,68</sup> Thus, with rare exceptions<sup>84</sup> (Chapter 44), bone marrow transplants have been successful only when the donor has been an identical twin or an HL-A identical sibling of the recipient.<sup>42,126,128</sup> Even with an HL-A-identical sibling donor, GvH disease of variable severity may appear, presumably because of non-HL-A differences.<sup>42,128</sup> The histocompatibility typing

data should always be confirmed by mixed leukocyte cultures<sup>8</sup> (page 504). Successful allogeneic bone marrow transplants have been reported in patients with leukemia, those with aplastic anemia, and in persons with immune deficiency diseases of various forms.<sup>38,42,127,128</sup>

### Fetal-Maternal Relations

Antileukocyte antibodies are frequently found in sera from pregnant and multiparous women (page 504); their production appears to be triggered by the paternal contribution to the fetal transplantation antigens.

*Neonatal leukopenia* (Chapter 42) due to anti-HL-A antibodies must be exceedingly rare, although leukopenia apparently may result from antibodies directed against granulocyte specific antigens.<sup>57,58,59</sup> On the other hand, *neonatal thrombocytopenia* (Chapter 34) may occasionally be due to anti-HL-A antibodies, or, at other times, to antibodies directed against platelet specific antigens (page 512).<sup>114,120</sup> This appears to be a rare occurrence, however.<sup>115</sup>

A clearcut relationship between the presence of antileukocyte antibodies in the mother and fetal abortion, stillbirth, neonatal deaths, and congenital malformations has not been established,<sup>41,113</sup> although one study suggested an association between *congenital malformations* and the presence of maternal anti-HL-A antibodies.<sup>77</sup> The antibodies may, however, have been the result rather than the cause of the malformations.

*Gestational choriocarcinoma* is a unique malignant disease since it is of fetal origin and must therefore be considered an allogeneic graft. Thus, rejection should in most cases be expected and spontaneous regression, even when metastases are present, has been observed.<sup>30</sup> In keeping with this a correlation has been found between the degree of lymphocytic infiltration of the tumor and the chances of recovery.<sup>29</sup>

The quality of antitumor immunity in patients with choriocarcinoma must, at least in part, be a function of the histocompatibility

difference between the fetus (ie, the paternal haplotype) and the mother. Preliminary studies have indeed suggested that when husbands have haplotypes identical to those of the spouse, prognosis is poor, whereas it is much better when no haplotypes are shared.<sup>54</sup> In addition, fewer HL-A incompatibilities have been found in persons with generalized disease than in those having localized disease.<sup>73</sup> In other studies no such correlations have been found.<sup>110</sup> A restricted distribution of HL-A antigens may explain the 10- to 20-fold higher incidence of trophoblastic disease among Greenland Eskimos than among Caucasians; 81% of Greenland Eskimos were found to be HL-A9 positive, and some of the Four antigens were also noted to be much more frequently present in these people.<sup>74</sup> This implies a greater chance for Eskimo children to be HL-A compatible with their mother.

### Paternity Testing

The HL-A system now fulfills most of the requirements for use in the exclusion of paternity.<sup>82</sup> In general terms, a man is excluded if both he and the baby's mother lack an antigen that the baby has, or if antigens he has and must hand on are not present in the child.<sup>74</sup> It is possible that HL-A typing may eventually become more informative than erythrocyte typing.<sup>50</sup>

### Relation to Human Diseases

An association between histocompatibility antigens and susceptibility to a variety of diseases, including malignant lesions, has been clearly documented in animal systems.<sup>54</sup> In man, similar associations appear to exist. Those of hematologic interest include acute lymphoblastic leukemia,<sup>96,139,140</sup> chronic lymphocytic leukemia, and lymphosarcoma,<sup>89,140</sup> as well as Hodgkin's disease.<sup>2,36,140,143</sup> Such an association is of great interest in view of the well-established linkage between histocompatibility antigens and immune responses towards well-defined antigens in at least two animal systems.<sup>65</sup> Thus it is possible that the

association between susceptibility to childhood leukemia or other malignant disease and certain HL-A antigens has an immunologic basis.<sup>28</sup>

## Leukocyte Transfusions

Leukocyte transfusions are given under two circumstances: (1) in granulocytopenia when neutrophils are the desired cells and (2) in immune deficiency states (Chapter 44) when lymphocytes or their precursors are grafted in an attempt to establish normal immune responses. Lymphocytes have also been transfused as part of the experimental immunotherapy of tumors (Chapter 55).

The potential benefit of *granulocyte transfusions* has long been recognized in patients suffering from agranulocytosis and sepsis,<sup>196</sup> but the widespread clinical application of such therapy has been difficult to realize. This is due to several major problems: (1) Since the concentration of neutrophils in normal blood is approximately 1/1000 of that of red cells and 1/100 that of platelets, the collection of large numbers of cells is difficult. (2) The life span of the neutrophil in the blood is but a few hours, usually less than 10 (see Chapter 6). (3) The recovery of transfused neutrophils often is very poor, and the survival much less than 10 hours because of the presence of antileukocyte antibodies or the sequestration of cells in extravascular sites such as the liver and spleen. However, *improvements in collection techniques now* permit the routine harvest of large numbers of leukocytes from single donors.<sup>152,161,173,180,184</sup> and HL-A typing and cross-match techniques allow for better donor selection.<sup>170,174</sup> Under these circumstances, leukocyte transfusions result in a detectable increase in the number of circulating granulocytes and may lead to more effective control of infections.

### Indications

The routine use of platelet transfusions has made infection the leading cause of death in patients with hematologic malignant dis-

ease<sup>174</sup> (Chapter 54). While the introduction of the newer antibiotics has lowered the mortality rate of patients with gram-negative sepsis from 62 to 90%<sup>154,159 163 184,203</sup> to 29 to 38%,<sup>153 191</sup> the risk of death remains substantial both for gram-negative and other infections. Leukocyte transfusions may help to further decrease this risk.<sup>168 174 193</sup>

The most common indication for leukocyte transfusions is, therefore, bacterial sepsis that is unresponsive to appropriate antibiotic therapy and occurs in association with *severe leukopenia* due to primary disease of the marrow, or myelosuppression due to cytotoxic drugs. In addition, patients with granulocytopenia due to a variety of drug reactions (Chapter 41) and patients with aplastic anemia may benefit from granulocyte transfusions when they develop severe infections.<sup>194</sup> When neutropenia is due to increased rates of neutrophil destruction, as in congestive splenomegaly or in the presence of leukocyte antibodies (Chapter 42), leukocyte transfusions are probably without appreciable effect. Granulocyte transfusions may also be of benefit to patients suffering from *disorders of leukocyte function*, such as chronic granulomatous disease.<sup>190</sup> The induction of remissions following leukocyte transfusion in patients with leukemia has also been reported,<sup>151,179,202</sup> although leukemia does not, at present, constitute a valid indication for this form of treatment. The cause of such remissions is not clear, but graft-versus-host reactions<sup>192</sup> and feed-back inhibition<sup>158</sup> have been postulated as possible mechanisms.

### Selection of Donors

Potential cell donors should be free of disease that is transmissible by transfusion. The following are additional requirements: (1) The HL-A type of the donor and of the recipient should be determined. (2) Donors and recipients should be red-cell-type compatible and should have a negative red-cell cross-match (page 472). (3) Each recipient must be examined for the presence of antibodies against donor leukocytes. This can be done by leukocyte cytotoxicity<sup>72</sup> or leuko-

agglutination techniques.<sup>169</sup> If the recipient has antibodies against a potential donor, the latter's leukocytes should not be used since the intravascular sojourn of such cells is extremely brief. (4) Wherever possible, family members such as siblings and parents should be used as donors. Frequently, the need for leukocyte transfusions can be anticipated and leukocyte typing of family members will allow selection of the most histocompatible donor; the most desirable donor is, of course, a sibling with an identical HL-A phenotype (page 502).

### Collection of Granulocytes

#### From CML Donors

When more sophisticated techniques are not available, patients with chronic myelocytic leukemia in relapse are useful sources of large numbers of granulocytes,<sup>155 166,188</sup> since it is impractical to obtain adequate numbers of normal white cells without special techniques. Even under optimal conditions, 40 units of normal blood would have to be processed to obtain the same number of leukocytes recovered from one unit of leukemic blood.<sup>204</sup> It has been stated that leukemic leukocytes may not be as efficient as normal cells in fighting infection,<sup>182 190</sup> but this may be related in part to extracellular causes such as antileukocyte antibodies. Good intravascular survival, extravascular migration, and phagocytic function have been reported in recipients without preformed antibodies.<sup>166</sup>

CML leukocytes may be obtained by standard *leukopheresis techniques*, using plastic collecting bags and ordinary ACD anticoagulant. The buffy coat is obtained by differential centrifugation, the red cells are returned to the donor, and another unit of blood is obtained. Most donors tolerate leukopheresis of at least 2 or 3 units at a single sitting, but the procedure is time consuming. The collection of CML granulocytes by other techniques is discussed below. Since CML donors are almost invariably poor HL-A matches with the recipient, the effi-

ciency of such transfusions is reduced once antileukocyte antibodies develop (see below).

### From Healthy Donors

Improved collection techniques have now made it possible to recover adequate numbers of leukocytes from healthy donors and these are to be preferred whenever possible. The techniques of continuous flow centrifugation (CFC)<sup>152 153 173 184</sup> or filtration leukopheresis (FL, reversible leukoadhesion)<sup>161 176</sup> permit the collection of large numbers of normal granulocytes from a single donor. CFC allows for the rapid processing of blood (40 ml/min) and the collection efficiency is good: approximately one third of CML granulocytes and one fourth of normal donor granulocytes are recovered. At a single sitting,  $10^{10}$  normal cells and  $10^{11}$  leukemic cells are easily collected. Between 55 and 66% of these cells will be mature granulocytes.

In general, CFC is to be preferred to FL collections, but the FL technique is simpler and more readily available. CFC-collected leukocytes have normal intravascular survival ( $t_{1/2} = 6.5$  hours) and appear to function normally after transfusion.<sup>174</sup> In contradistinction, FL-collected leukocytes yield lower increments after transfusion, their hexose monophosphate shunt activity and bactericidal capacity are somewhat reduced *in vitro*, and they may well have abnormal intravascular survival patterns.<sup>174,180</sup> In addition, most recipients of FL-collected leukocytes develop chills and fever after transfusion, even though donors are carefully selected.<sup>174</sup>

### Transfusion of Granulocytes

Following collection, granulocytes should be transfused as quickly as possible. Employing the number of granulocytes available from single histocompatible donors (about  $10^{10}$ ) it is possible to achieve median one-hour transfusion increments of 250 to 850 granulocytes/ $\mu$ l/ $m^2$  of body surface.<sup>175</sup> However, the percent recovery of leukocytes

one hour after transfusion is closely linked to the goodness of the match. Median recovery of HL-A and ABO identical leukocytes is 50%, but there is a progressive decrease as the number of mismatched HL-A antigens increases—28% with one mismatch, 17% with two mismatches, and only 3% with three mismatches—even in the absence of demonstrable leukoagglutinins.<sup>171</sup> When leukoagglutinins are present, the recovery is very low. In addition, the recovery of transfused leukocytes is compromised when HL-A matched but ABO mismatched leukocytes are transfused (7%). The importance of HL-A compatibility also is reflected in the poor recovery of CML leukocytes (median 5%),<sup>169 186,192</sup> both in the presence (<1%) and absence (15%) of preformed antibodies.<sup>169 170 188</sup> Patients with preformed antibodies may have severe transfusion reactions and bacterial killing may be reduced.<sup>169 170 188</sup> Antileukocyte antibodies are most often the result of multiple transfusions but may also follow pregnancy, or organ transplantation; occasionally their presence is unexplained.

Because transfusion of viable lymphocytes into immunosuppressed patients may lead to accidental engraftment and an ensuing graft-versus-host disease,<sup>171</sup> most clinicians prefer to irradiate the leukocytes with 1,500 rads before transfusion.<sup>174</sup> It is possible, however, that irradiation may impair the phagocytic function of neutrophils (Chapter 42).

Whenever possible, granulocyte transfusions should be repeated daily until the infection is under control; a progressive improvement in patient survival has been reported with increasing numbers of transfusions.<sup>174,175</sup> Significant benefit from leukocyte transfusions has been claimed in reports of several studies,<sup>168,193</sup> although accounts of strictly randomized trials have not yet been published. It would seem reasonable, however, on the basis of available evidence, to support septic patients who are leukopenic with well-matched granulocyte transfusions wherever these are available.

## Complications

Complications range from mild acute reactions such as *fever* and *chills* to severe reactions with *respiratory distress*, retrosternal constriction, pallor, and cyanosis. Respiratory distress is presumably due to sequestration of agglutinated leukocytes within the pulmonary microvasculature.<sup>164,176</sup> Transient *pulmonary infiltrates* may also occur in the presence of leukoagglutinins.<sup>201</sup> Several types of infections have been transferred by leukocyte transfusions, including malaria<sup>162</sup> and toxoplasmosis<sup>193</sup>; serum hepatitis has not been clearly documented, but undoubtedly occurs.

## Platelet Antigens

Several systems of antigenic determinants are found on the surface of platelets.<sup>269</sup> These include (1) the HL-A antigens, which are shared with leukocytes and other tissues; (2) ABO antigens, which are shared with red cells; and (3) platelet-specific antigens. All of these antigens are detected by means of isoantibodies formed after transfusion or pregnancy. In addition, immunization of dogs, rabbits, guinea pigs, and chickens with human platelets yields heterologous anti-platelet antisera,<sup>233,234,264</sup> but the specificities detected by these have not been further delineated and their clinical significance is unknown. They will not be discussed further.

### HL-A Antigens

In 1962, Shulman and coworkers studied sera from two women whose babies suffered from neonatal thrombocytopenia and found that these sera reacted with platelets from 49 normal individuals. The corresponding antigen was called Pl<sup>B1</sup> (later PlGrLy<sup>B1</sup>) and appears to be inherited as a dominant character in the two families studied. Later this antigen was found to be the same as the histocompatibility antigen Mac (= HL-A2).<sup>45</sup> Subsequently, other histocompatibility antigens were shown to be present on platelets and now all currently known LA (First

series) antigens and most Four (Second series) antigens (Table 12-1) are known to be represented.<sup>269</sup> It seems reasonable to suggest that eventually all HL-A isoantigens will be detectable on platelets. Indeed, platelet typing represents a simple and reliable alternative to leukocyte typing, even for purposes of organ transplantation (page 514). The most important older designations for platelet antigens and their current HL-A equivalents are listed in Table 12-3.
